shared with other viruses. For example, the replication of HIV and the stages that have been targeted by approved antiviral drugs are illustrated in Figure 13.2. In principle, any stage can be targeted for inhibition. There are potential advantages to targeting very early or late stages such as attachment, entry, and release, because inhibitors of these stages do not have to enter cells to exert activity. Stages such as genome replication, assembly, and maturation often require specific viral enzymes, which, as described earlier, are attractive drug targets. Indeed, most antiviral drugs currently available inhibit genome replication. Nevertheless, there are antiviral drugs that act at nearly every stage of viral infection.

Inhibition of Viral Attachment and Entry

Inhibition of attachment and entry prevents all subsequent steps in virus infection and permits the virion to be cleared by immune and other mechanisms. There have been two general approaches for drugs that inhibit attachment and entry, which thus far have resulted in two approved anti-HIV drugs:

maraviroc and enfuvirtide. Both of these drugs have unusual properties; maraviroc targets a host protein, whereas enfuvirtide is a peptide.

CCR5 Blockers

Maraviroc (Fig. 13.3) is a CCR5 blocker; it inhibits binding of HIV to the CCR5 co-receptor. CCR5 is the co-receptor used by the most commonly transmitted HIV-1 strains (R5 tropic), which predominate during the early stages of HIV-1 infection.²⁶ There are several attractive features to CCR5 as a target for anti-HIV drugs: Knockout mice lacking CCR5, and humans with homozygous deletions in the gene encoding CCR5 (CCR5Δ32) lack detectable abnormalities, suggesting that blocking this host function might not have adverse consequences.³⁸ Certain of these CCR5Δ32 homozygotes who have been highly exposed to HIV have remained uninfected, and their cells are resistant to R5-tropic strains of HIV *in vitro*.²²¹ Blockade of CCR5 with a natural ligand (e.g., RANTES) or antibody inhibits R5-tropic HIV replication (e.g.,⁵⁶). These observations suggested that

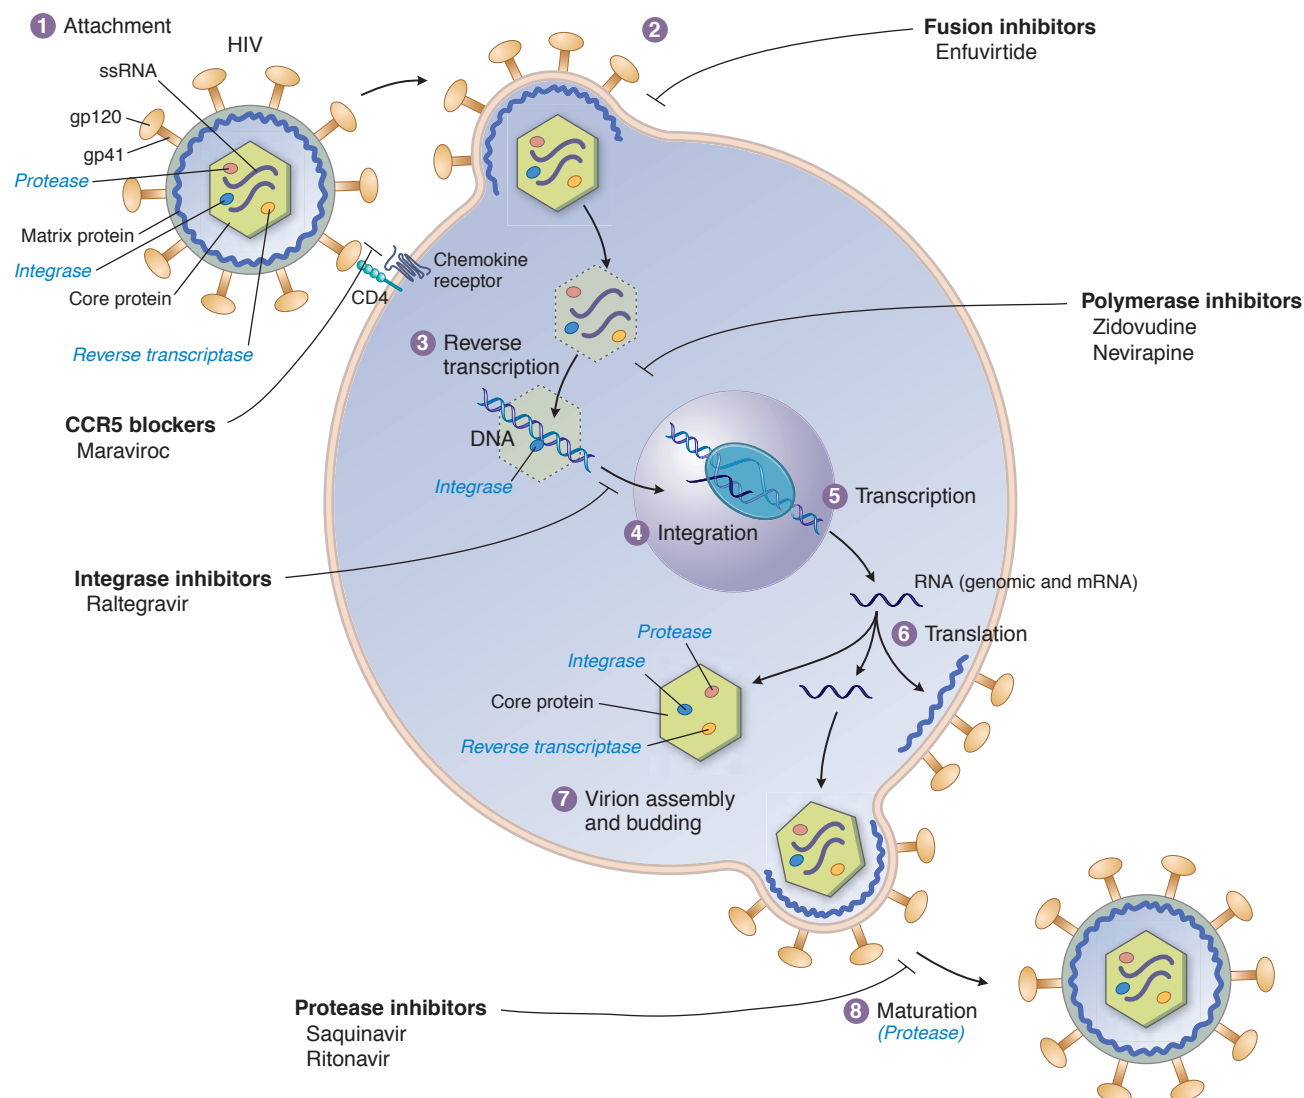

FIGURE 13.2. Stages of HIV infection blocked by different classes of antiviral drugs. The lifecycle of HIV is cartooned, showing the following. **1:** Virus attachment is dependent on binding interactions between viral gp160 (composed of gp41 and gp120 proteins) and host cell CD4 and certain chemokine receptors. **2:** Fusion of the viral membrane (envelope) with the host cell plasma membrane allows the human immunodeficiency (HIV) genome complexed with certain virion proteins to enter the host cell. **3:** Uncoating permits the single-stranded RNA (ssRNA) HIV genome to be copied by reverse transcriptase into double-stranded DNA. **4:** The HIV DNA is integrated into the host cell genome, in a reaction that depends on HIV-encoded integrase. **5:** Gene transcription and posttranscriptional processing by host cell enzymes produce genomic HIV RNA and viral messenger RNA (mRNA). **6:** The viral mRNA is translated into proteins on host cell ribosomes. **7:** The proteins and genomic RNA assemble into immature virions that bud from the host cell membrane. **8:** The virions undergo proteolytic cleavage, maturing into fully infective virions. The steps at which classes of anti-HIV drugs act (attachment, fusion, reverse transcription, integration, and maturation) are indicated, with examples from specific drug classes provided. (Modified from Yeh RW, Coen DM. Pharmacology of viral infections. In: Golan DE, Tashjian AH, Jr., Armstrong EJ, et al., eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. Third edition. Philadelphia: Lippincott Williams & Wilkins, 2012:649–673.)

blocking CCR5 could be efficacious against R5-tropic HIV without causing much toxicity.

Maraviroc was discovered using high-throughput screening for small molecules that block binding of CCR5 to a natural ligand, followed by medicinal chemistry efforts to improve upon a hit from the screen.⁸³ Modeling and mutational studies suggest that maraviroc and several other CCR5 blockers bind

to a pocket on CCR5 formed by transmembrane domains,¹⁹⁵ and allosterically inhibit binding to HIV gp120, thereby blocking HIV entry (Fig. 13.3).^{9,83,112,374} R5 tropic HIV mutants resistant to CCR5 blockers including maraviroc contain altered gp120 molecules that are able to bind to the drug-bound form of CCR5.^{366,374} Maraviroc was approved in 2007 for use in combination with other anti-HIV drugs in patients with R5-tropic

FIGURE 13.3. Model for HIV gp41-mediated fusion and maraviroc and enfuvirtide (T-20) action. **A:** Human immunodeficiency virus (HIV) glycoproteins exist in trimeric form in the viral envelope. Each gp120 molecule is depicted as a ball attached noncovalently to gp41. The CD4 receptor and a chemokine receptor that serves as a co-receptor in the host cell plasma membrane are shown. **B:** The binding of gp120 to CD4 and the co-receptor causes a conformational change in gp41 that exposes the fusion peptide, heptad-repeat region 1 (HR1) and heptad-repeat region 2 (HR2). The fusion peptide inserts into the host cell plasma membrane. **C:** gp41 undergoes further conformational changes, characterized by unfolding and refolding of the HR2 segments. **D:** Completed refolding of the HR regions creates a hemifusion stalk in which the outer leaflets of the viral and host cell membranes are fused. **E:** Formation of a complete fusion pore allows viral entry into the host cell. **F:** Enfuvirtide (T-20) is a synthetic peptide that mimics HR2 and binds to HR1. It prevents the HR1–HR2 interaction (dashed arrow). The drug, therefore, traps the virus–host cell interaction at the attachment stage, preventing membrane fusion and viral entry. **G:** Maraviroc is a small molecule antagonist of the CCR5 chemokine receptor; the drug blocks cellular infection of HIV strains that use CCR5 for attachment and entry (dashed arrow from **A** to **G**). The structure of maraviroc is shown. (From Yeh RW, Coen DM. Pharmacology of viral infections. In: Golan DE, Tashjian AH, Jr., Armstrong EJ, et al., eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. Third edition. Philadelphia: Lippincott Williams & Wilkins, 2012:649–673.)

strains. Therefore, patients must be tested to determine if they harbor virus that utilizes a different co-receptor (i.e., CXCR4). Maraviroc treatment failures are more frequently attributable to preexisting minority populations of CXCR4-tropic virus than to selection of R5-tropic virus that is resistant to maraviroc.²⁵⁹ Resistance to CCR5 blockers has not resulted thus far from R5-tropic virus evolving to use a different co-receptor. Nevertheless, this possibility and the effects of antagonizing a host function remain potential issues for the long-term clinical use of maraviroc and other CCR5 blockers, which are in development (e-Table 13.1).

Fusion Inhibitors: Enfuvirtide

Although compounds that bind to virus particles and block attachment and entry have been investigated in the laboratory and clinic for decades (e.g., the anti-picornavirus drug, pleconaril), enfuvirtide was the first drug approved for clinical use that acts this way. This agent was discovered by a rational, directed approach that examined the ability of peptides to inhibit HIV infection in cell culture.^{385,386} The peptide that was most potent (T-20) is similar to a segment of gp41, the HIV protein that mediates membrane fusion. The proposed mechanism for gp41-mediated membrane fusion and T-20 action is illustrated in Figure 13.3: The gp41 protein in the virion is ordinarily trapped in a metastable conformation so that it cannot fuse membranes or bind T-20. Binding of HIV to its cellular receptors triggers a conformational change that exposes the segment of gp41 that is thought to insert into host cell membranes (fusion peptide), a heptad repeat region (HR-1), and the segment that T-20 resembles, which is a second heptad repeat (HR-2). The gp41 then rearranges so that HR-1 and HR-2 bind to each other. If the fusion peptide has inserted into the host cell membrane, this refolding brings the virion envelope and the cell membrane in proximity, thereby allowing membrane fusion to occur (by mechanisms that remain incompletely understood). When T-20 is present, however, it binds to HR-1 and prevents the refolding process, thereby preventing fusion of the HIV envelope with the host cell membrane.

Although this model requires an exogenous peptide to compete with an intramolecular interaction to bind to a target that is available only transiently, it is supported by a number of observations. These include the crystal structure of the rearranged form of gp41, which shows the HR-1–HR-2 interaction^{41,357,373} and evidence that T-20 interacts with HR-1 containing peptides.^{42,205,384} Genetic studies show that HR-1 and HR-2 are crucial for fusion.^{88,383} Perhaps the strongest evidence that T-20 inhibits HIV replication by binding to HR-1 is that HIV mutations that confer resistance to T-20 alter HR-1 residues, and that these alterations weaken binding of T-20 to HR-1.³¹²

Not only is the mechanism of T-20 remarkable, but so is its development into a drug. Because it is a peptide, there were major obstacles to its large-scale synthesis and manufacture, and outpatients must mix the drug and inject it themselves. Regardless, it proved that inhibitors of attachment and entry can be effective antiviral agents.

Inhibition of Viral Uncoating: Adamantane Derivatives

The adamantanes, amantadine and rimantadine (Fig. 13.4), are active exclusively against influenza A virus (and not influenza B or C viruses). In most influenza A virus strains, these drugs

inhibit virus uncoating. It took decades to identify the target of these drugs. A key finding^{142,143} was that amantadine has an unusual dose–response curve, at least for some strains of influenza A virus. It inhibits viral replication at concentrations of approximately 1 μM , which are those attained in patients treated with the drugs; however, at somewhat higher concentrations, it loses antiviral activity. It then regains antiviral activity at concentrations greater than 100 μM . Hay and colleagues¹⁴² then showed that mutants that could replicate in 5 μM amantadine were resistant due to point mutations within the M segment of influenza RNA gene, in an open reading frame that had only recently been recognized. This open reading frame encodes a small membrane protein known as M₂ (the M segment also encodes the long-recognized matrix [M₁] protein.) Subsequent biochemical and electrophysiologic experiments showed that the M₂ protein forms a tetrameric, pH-gated channel for H⁺ ions and that amantadine and rimantadine block this channel.^{17,89,163,289,349}

The manner in which amantadine and rimantadine block the M₂ ion channel has been investigated intensively. Viral mutations conferring resistance to these drugs alter any of five residues in the transmembrane segment of the protein that are predicted to be within the pore of the channel, suggesting that the drugs bind to these residues and “plug” the channel.¹⁴¹ Structural studies of drug-bound versions of M₂ followed by electrophysiologic assays using *Xenopus* oocytes and assays of engineered viral mutants support this suggestion.^{36,180,270,343} However, evidence from nuclear magnetic resonance (NMR) studies and liposomal proton flux assays supported the suggestion that these drugs do not act as “plugs,” but instead bind to the outside of the channel and stabilize its closed conformation.^{287,330} This controversy appears to have been resolved in favor of the pore-binding site being the one that mediates drug action, with the NMR structure of rimantadine bound within the pore of a drug-sensitive chimeric M₂ derived from influenza A and B viruses.²⁸⁶

How would blocking an ion channel lead to inhibition of uncoating? A reasonable but not completely verified model is diagrammed in Figure 13.4. Influenza A virus attaches to sialic acid moieties on cell surface glycoproteins, and then, bound to its receptor, is internalized, surrounded by a cell membrane–bounded compartment, the endosome, which normally participates in membrane protein recycling. As part of its normal function, the endosome becomes acidified. During influenza virus entry, this reduction in pH causes a conformational change in the virion hemagglutinin protein, and fusion of the virion envelope and the endosomal membrane via a mechanism similar to that of HIV gp41 (Fig. 13.3). By itself, this action would release viral ribonucleoprotein into the cytoplasm. However, in the presence of amantadine or rimantadine, the matrix protein, M₁, does not dissociate from the ribonucleoprotein, which remains in the cytoplasm instead of entering the nucleus.^{34,236} Low pH can promote the dissociation of M₁, and allow nuclear entry of the ribonucleoprotein.³³ Therefore, M₂ in the virion envelope functions to let H⁺ ions from the acidified endosome enter the virion, and dissociate M₁ from the ribonucleoprotein. Amantadine and rimantadine would block the entry of H⁺ ions, thereby preventing this uncoating event.

With certain influenza A virus strains, amantadine and rimantadine also block late events in virus replication, in particular,

FIGURE 13.4. Model for uncoating of influenza A virus and effect of amantadine or rimantadine. The structures of amantadine and rimantadine are shown. The process of influenza A virus uncoating and drug action is depicted. The virus enters host cells by receptor-mediated endocytosis (not shown) and is contained within an early endosome. The early endosome contains a H⁺-ATPase that acidifies the endosome by pumping protons from the cytosol into the endosome. A low pH-dependent conformational change in the envelope protein, hemagglutinin (HA), triggers fusion of the viral membrane with the endosomal membrane. This fusion event, however, is not sufficient to cause viral uncoating. In addition, protons from the late endosome must enter the virion through the M₂ proton channel, which is a virion envelope protein that opens in response to acidification (pH-gated ion channel). The entry of protons into the virion causes dissociation of the M₁ matrix protein from the influenza A ribonucleoprotein (RNP), releasing it into the cytoplasm. The dissociation of matrix is required for RNP to be transported to the nucleus, where it is transcribed and replicated. Amantadine and rimantadine block M₂ ion channel function and thereby inhibit acidification of the interior of the virion, matrix dissociation, and uncoating. NA, neuraminidase. (Modified from Yeh RW, Coen DM. Pharmacology of viral infections. In: Golan DE, Tashjian AH, Jr., Armstrong EJ, et al., eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. Third edition. Philadelphia: Lippincott Williams & Wilkins, 2012:649–673.)

maintenance of hemagglutinin in a proper conformation for infectivity.¹⁴¹

Influenza virus mutants that are resistant to amantadine and rimantadine due to altered M₂ have been assayed in animal models including mice and ferrets, and show little or no diminution in their replication or pathogenesis.^{15,273,355} This correlates well with their behavior in human infections.¹⁴⁴ Since the discoveries of the mechanism of adamantanes and the function of M₂, a number of other viruses have been found to encode proteins that can form ion channels. These also might serve as good drug targets.

Inhibition of Viral Gene Expression: NS3/4A Protease Inhibitors

Viral gene expression entails not only the transcription of the viral genome into mRNA, the translation of mRNA into protein, and the stabilities of RNA and protein gene products, but can also include a variety of processing events including capping, splicing, and polyadenylation of viral mRNAs, and proteolytic cleavage of viral polyproteins into their individual protein units. Many viruses encode functions that execute or abet one or more of these steps in gene expression, and much

FIGURE 13.5. Anti-HCV (hepatitis C virus) protease inhibitors. The structures of telaprevir (**left**) and boceprevir (**right**) are shown at the **top** of the figure. A schematic of the interaction of telaprevir with the HCV NS3/4A protease is shown at the **bottom** of the figure. Important hydrogen-bonding interactions between protease residues and drug are shown with dashed lines, whereas protease residues that make important hydrophobic interactions are indicated in green. The covalent bond formed between telaprevir and serine 139 of NS3 is highlighted in yellow. (Courtesy of Ayesegui Özen and Celia Schiffer, based on the crystal structure of telaprevir bound to NS3/4A. From Romano KP, Ali A, Soumana D, et al. The molecular basis of drug resistance against hepatitis C virus NS3/4A protease inhibitors. *PLoS Pathog* 2012;8:e1002832.)

effort has gone into targeting these functions for development of antiviral drugs. In particular, viral proteases that generate individual viral proteins have been targeted. The activity of one of these, the HIV protease, is not required until the viral particle is fully assembled, and thus will be discussed under the heading Inhibition of Viral Assembly and Maturation below. The activity of the HCV NS3/4A protease, however, is required for proper expression of viral gene products for essentially all subsequent steps in viral infection. In 2011, the first drugs that target this stage of viral replication were approved by the U.S. Food and Drug Administration (FDA). These two drugs—telaprevir and boceprevir (Fig. 13.5)—are peptidomimetics that inhibit the NS3/4A protease.

Following entry and uncoating of HCV, its genome serves as an mRNA that is translated into a very large (~3,000 residue) polyprotein. This polyprotein is processed into 10

individual proteins by cellular and viral proteases. One viral protease, which is especially important for generating non-structural (NS) proteins, is NS3. NS3 contains an N-terminal protease domain and a C-terminal helicase domain. A second protein, NS4A, forms a complex with NS3 (NS3/NS4A), and enhances its protease activity. During polyprotein processing, NS3 autoproteolytically cleaves between NS3 and NS4A, and then cleaves to generate NS4A (its co-factor), NS4B, NS5A, and NS5B. The NS proteins are essential for HCV genome replication and production of infectious virus. These proteins, especially NS3, are also thought to counteract the innate immune response.¹⁰⁹

Given the success of drugs that inhibit the HIV protease (see below), investigators launched efforts to develop drugs that inhibit the NS3 protease. As described below in more detail for the HIV protease inhibitors, the development

process was iterative involving the synthesis of candidate inhibitors, solving the structures of these inhibitors bound to the protease, and then designing new compounds with higher potency and better pharmacological properties based on those structures.^{213,266} Several features of the HCV NS3/4A protease and its inhibitors differ from those of their HIV counterparts, however. The HIV protease is an aspartyl protease, whereas the NS3/4A protease is a serine protease. The HIV protease's substrate binding pocket is deep, so that there are multiple opportunities for interactions with a small molecule inhibitor, whereas the NS3/4A binding pocket is shallow, with relatively few obvious sites for binding a small molecule. Despite this obstacle, structure-based medicinal chemistry efforts identified sites on NS3 that could mediate tight and selective binding of inhibitors (Fig. 13.5).^{213,266} The anti-HIV protease inhibitors are largely symmetrical, mimicking the protein substrate on both sides of the protease cleavage site, whereas the anti-NS3/4A inhibitors are relatively asymmetric, mainly mimicking the N-terminal product of protease cleavage. The anti-HIV protease inhibitors contain CHOH moieties that mimic the transition state of protease catalysis to achieve tight, but non-covalent binding to the enzyme (transition state analogs). In contrast, the anti-NS3/4A inhibitors contain ketoamide groups that react with the catalytic serine of the enzyme to form a covalent bond with the enzyme (Fig. 13.5), which only very slowly reverses, resulting in time-dependent inhibition of the enzyme (mechanism-based inhibitors) and inhibition constants of ~10 nM.^{213,266}

Both boceprevir and telaprevir exhibit submicromolar potencies (concentrations that inhibit replication by 50%) for inhibition of replication of HCV genomes in a cell-based replicon system.^{214,229} Interestingly, telaprevir was considerably less potent in these assays than a macrocyclic NS3/4A inhibitor, BILN 2061, which binds tightly but noncovalently; yet both drugs eliminated HCV replicons (10⁴-fold reductions) from cells at similar concentrations, which may relate to the very slow reversibility of telaprevir.²¹⁴ This observation helps to illustrate the concept that efficacy (how much viral replication is reduced) is likely to be more important than potency in antiviral development. Both boceprevir and telaprevir inhibit HCV genome replication, at least additively in combination with interferon α (IFN- α).^{214,229} These findings are important due to the use of boceprevir and telaprevir in combination with IFN- α for HCV therapy, and they may relate to a role for NS3 in counteracting IFN action.¹⁰⁹ Once a suitable cell culture system that supports complete replication of HCV was devised, it was shown that NS3/4A inhibitors block production of infectious virus.²¹⁵ Finally, as was first strikingly demonstrated with BILN 2061, NS3/4A inhibitors can drastically reduce levels of HCV in the plasma of patients.¹⁹⁷

HCV replication is rapid and error-prone; therefore, it is not surprising that resistance to NS3/4A protease inhibitors arises rapidly both in cell culture systems and in patients.⁸² Indeed, resistant variants preexist in untreated patients.¹⁴ The different subtypes of HCV complicate HCV drug resistance, with protease inhibitors having different potencies against different subtypes, and with different subtypes requiring different numbers of mutations to achieve resistance.¹³²

Several mutations confer resistance to boceprevir and telaprevir, with some altering NS3 residues that make direct contacts with drug and others altering more distant residues that

contact amino acids close to the drug, such as the catalytic serine.¹³² Certain mutations confer differing degrees of resistance to the two drugs. Notably, some mutations that confer resistance to boceprevir and telaprevir do not confer resistance to newer macrocyclic NS3/4A inhibitors that are in development (e-Table 13.1), and certain mutations that are resistant to the macrocyclic inhibitors do not confer resistance to boceprevir and telaprevir. However, other mutations confer resistance to both classes of NS3/4A drugs.¹³² The effects of the different mutations on fitness vary as measured in cell culture systems for genome replication and production of infectious virus or in human hepatocyte chimeric mice, with some mutations being clearly impaired and others having very little impact.^{158,334,363} Mathematical modeling of HCV infections in humans suggests that at least some protease inhibitor-resistant mutations retain substantial fitness.³¹⁶ These features of resistance to boceprevir and telaprevir are an impetus for continued development of anti-HCV drugs that can be used in combination (e-Table 13.1).

Inhibition of Viral Genome Replication

Most antiviral drugs inhibit viral genome replication, and nearly all of these inhibit a viral polymerase. Those viruses whose genome replication has been successfully targeted to yield FDA-approved drugs include certain human herpesviruses, the retrovirus HIV, and the hepadnavirus HBV. Several inhibitors of the polymerase of the flavivirus HCV are in clinical development. Most of the approved drugs are nucleoside analogs (Figure 13.6). Some of these nucleoside analogs actually mimic nucleoside monophosphates, so they are actually nucleotide analogs. A few approved drugs are nonnucleoside inhibitors of DNA polymerase or reverse transcriptase that act by binding at a site other than the dNTP-binding site, and one approved drug inhibits HIV integrase.

Nucleoside Analogs

Nucleoside analogs that clearly act by inhibiting viral polymerases are approved for treatment of herpesviruses, HBV, and HIV, and several are in development for treatment of HCV. Another nucleoside analog, ribavirin, is used clinically against HCV and respiratory syncytial virus, but its mechanism of action against those viruses is not well understood (see below). All nucleoside and nucleotide analogs must be activated by phosphorylation, usually to the triphosphate form, to exert their effect. Phosphorylated nucleoside analogs inhibit polymerases by competing with the natural substrate (dNTP for DNA polymerase) and are usually also incorporated into the growing nucleic acid chain, where they often terminate elongation. Either or both of these features—inhibition and incorporation—can be important for antiviral activity.

The more efficiently cellular enzymes phosphorylate the nucleoside analog and the more potently the phosphorylated forms act against cellular enzymes, the more toxic the nucleoside analog will be. Selectivity, therefore, is dependent upon how much more potently and effectively viral genome replication is inhibited than are cellular functions, and for the herpesviruses, how much more efficiently viral enzymes phosphorylate the drug than do cellular enzymes.

Anti-Herpesvirus DNA Polymerase Inhibitors

The various human herpesviruses encode both kinases and DNA polymerases. The kinases are usually not essential for viral

A Native nucleosides

C Anti-HIV and anti-HBV nucleoside and nucleotide analogues

D Anti-RNA virus nucleoside analogue

FIGURE 13.6. Structures of antiviral nucleoside analogues. **A:** The deoxynucleosides used as precursors for DNA synthesis are depicted in their *anti* configurations. The base moieties are shaded. **B:** Anti-herpesvirus nucleoside analogs mimic the deoxynucleoside, deoxyguanosine, except for cidofovir, which mimics the deoxynucleotide dCMP. The compounds shown here all contain acyclic moieties that mimic deoxyribose. Valacyclovir and famciclovir are prodrugs of acyclovir (ACV) and penciclovir, respectively. **C:** Anti-HIV (human immunodeficiency virus) and anti-HBV (hepatitis B virus) nucleoside analogs mimic dT, dC, dA, and dG except for tenofovir, and adefovir, which mimic dAMP. All of the analogs contain a base found in **A**, except for didanosine, which mimics deoxyinosine and is converted to dideoxyadenosine, and abacavir, which contains a cyclopropyl-modified guanine. Tenofovir and adefovir are shown as their disoproxil and dipivoxil prodrugs, respectively. Lamivudine, emtricitabine, and telbivudine are L-stereoisomers, whereas the other nucleoside analogs and dT, dC, dA, and dG are D-stereoisomers. All of the compounds shown except entecavir contain deoxyribose mimics that lack the equivalent of a 3'-hydroxyl, and thus are obligate chain terminators. The anti-HIV nucleoside analogs, lamivudine and tenofovir(*), and telbivudine, adefovir, and entecavir (†) are approved for use against HBV. **D:** Ribavirin, which contains a purine mimic attached to ribose, is approved for use against the RNA viruses hepatitis C virus and respiratory syncytial virus. (Modified from Yeh RW, Coen DM. Pharmacology of viral infections. In: Golan DE, Tashjian AH, Jr., Armstrong EJ, et al., eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. Third edition. Philadelphia: Lippincott Williams & Wilkins, 2012:649–673.)

replication, but the catalytic subunits of the polymerases (Pols) are. These enzymes differ enough from their cellular counterparts to permit development of selective antiviral nucleoside analog.

A number of antiviral nucleoside analogs including vidarabine, idoxuridine, and trifluridine, were developed and used against HSV infections. However, these drugs have been superseded by more selective compounds, and their mechanisms will not be discussed further.

Acyclovir and Related Drugs

ACV is the paradigmatic antiviral nucleoside analog that illustrates many of the principles of nucleoside analogs. It consists of a guanine base attached to an acyclic sugar-like molecule (Fig. 13.6). ACV and its more orally available valine ester, valacyclovir, and the related drugs, penciclovir and its orally available derivative, famciclovir (structures in Fig. 13.6) have similar mechanisms of action against HSV and VZV. ACV was originally synthesized at Burroughs Wellcome as part of a program to discover adenosine deaminase inhibitors, and only later was it tested for antiviral activity. The mechanism of ACV action⁹¹ is presented in Figure 13.7. The TK encoded by HSV and VZV phosphorylates ACV, despite its differences from the natural substrate of this enzyme, thymidine (also known as deoxythymidine; see Fig. 13.6). Crystal structures of HSV TK in complex with thymidine or ACV^{29,40,387} show that the guanine moiety of ACV interacts with the same residues as does the thymine moiety of thymidine, albeit with differences in water-mediated binding and bond angles. Despite this, ACV is not a particularly good substrate for HSV or VZV TK. Nevertheless, no mammalian enzyme phosphorylates ACV nearly as efficiently as the HSV and VZV TKs. Accordingly, HSV- and VZV-infected cells contain 30- to 100-fold more phosphorylated ACV than do uninfected cells, which accounts for much of ACV's antiviral selectivity.

Phosphorylation of ACV by the viral TK produces the compound ACV-monophosphate, which is converted sequentially to ACV-diphosphate and ACV-triphosphate (ACV-TP) by cellular enzymes.^{252,253} ACV-TP then inhibits HSV and VZV DNA polymerases. Inhibition of HSV DNA polymerase *in vitro* is a three-step process (Fig. 13.7).³⁰⁰ In the first step, ACV-TP competitively inhibits deoxyguanosine triphosphate (dGTP) incorporation (high concentrations of dGTP can reverse inhibition at this early step). Next, ACV-TP acts as a substrate and is incorporated into the growing DNA chain opposite a C residue. Finally, the polymerase translocates to the next position on the template, but cannot add a new deoxynucleoside triphosphate because ACV contains no 3'-hydroxyl; hence ACV-TP is an obligate chain terminator. Provided that the next dNTP is present, the viral polymerase freezes at this final step in a "dead-end complex," leading to apparent inactivation of the enzyme. There is biochemical evidence for selectivity at each of these steps, especially the third.^{174,235,299} The results of enzymological studies of viral polymerases from ACV-resistant mutants¹⁶⁷ argue that in infected cells, as *in vitro*, ACV-TP is not simply a competitive inhibitor of viral DNA polymerase, but rather that its incorporation is crucial, consistent with the three step model (Fig. 13.7).

Stocks of most HSV-1 strains contain ACV-resistant mutants at a level of about 0.01% to 0.1% (reviewed in 57). For at least certain HSV-2 strains, mutation frequencies are an order of magnitude higher.³²³ Compared with the drugs

discussed so far, there is considerable variety in ACV-resistant mutants. ACV selects mainly for *tk* mutants^{60,324,354} that ablate (TK-negative) or reduce (TK-partial) TK activity or alter TK so that it fails to phosphorylate ACV, but continues to phosphorylate dT (TK-altered). ACV-resistance mutations can also alter the viral polymerase to be less inhibited by the drug (reviewed in 199). Crystallographic studies have provided details on how *tk* and *pol* mutations affect binding and catalysis.^{29,40,102,167,222,387}

Nearly all ACV-resistant HSV mutants exhibit some degree of attenuation in assays of pathogenesis in animal models (reviewed in 58 and 199). TK-negative mutants are generally the most attenuated, especially for replication in sensory ganglia and reactivation from latency in those ganglia. However, certain clinical isolates are able to reactivate despite being TK negative.^{123,164} TK-partial mutants are less attenuated. As little as 5% to 10% of wild-type levels of TK activity permit normal ganglionic replication and reactivation from latency,^{44,59} and very low levels of TK produced via these translational mechanisms can suffice to permit some reactivation from latency.^{19,123} Interestingly, certain nonsense and frameshift mutations that might be expected to inactivate TK do not do so. This "leakiness" can result from translational mechanisms, including reinitiation and ribosomal frameshifting, that permit low levels of TK despite these mutations.^{124,165,171,176} Therefore, several mutants that would be expected to be TK negative are actually TK partial. TK-altered and *pol* mutants include the most pathogenic drug-resistant mutants, but some *pol* mutants are highly attenuated.

This picture becomes even more complicated when mixtures of drug-resistant mutants with each other or with drug-sensitive virus are considered, as these can complement each other for both drug resistance and pathogenicity.^{58,199} In addition, *tk* frameshift mutations in homopolymeric sequences, which are the most common drug-resistance mutations, tend to revert, sometimes at remarkably high rates, resulting in mixed populations that reactivate from latency.^{122,124,326} Therefore, it is important to consider heterogeneity as a factor influencing drug resistance and pathogenicity.

Ganciclovir and Valganciclovir

Although ACV has been highly successful in treating HSV and VZV disease, it is much less potent against HCMV,⁷⁴ which causes serious diseases in immunocompromised persons. This is primarily because much less phosphorylated ACV accumulates in HCMV-infected cells than in HSV- or VZV-infected cells.¹⁰⁶ This helped spur the development of ganciclovir. Ganciclovir is much more potent against HCMV than is ACV^{47,336} and was the first drug approved for use against HCMV. Ganciclovir is now also produced as the more orally available agent valganciclovir (see Fig. 13.6).

Ganciclovir, unlike ACV, but like penciclovir, has the equivalent of a 3'-OH moiety (see Fig. 13.6). Much as phosphorylated ACV accumulates in HSV-infected cells, phosphorylated ganciclovir accumulates in HCMV-infected cells.^{21,104} However, as HCMV does not encode a TK, this phosphorylation was initially thought to be due to induction of a host cell kinase. However, studies of a ganciclovir-resistant mutant led to the discovery that an unusual HCMV protein kinase (UL97) phosphorylates ganciclovir in infected cells.^{152,219,248,350,356} Cellular kinases can convert ganciclovir monophosphate to ganciclovir triphosphate. Like ACV triphosphate, ganciclovir

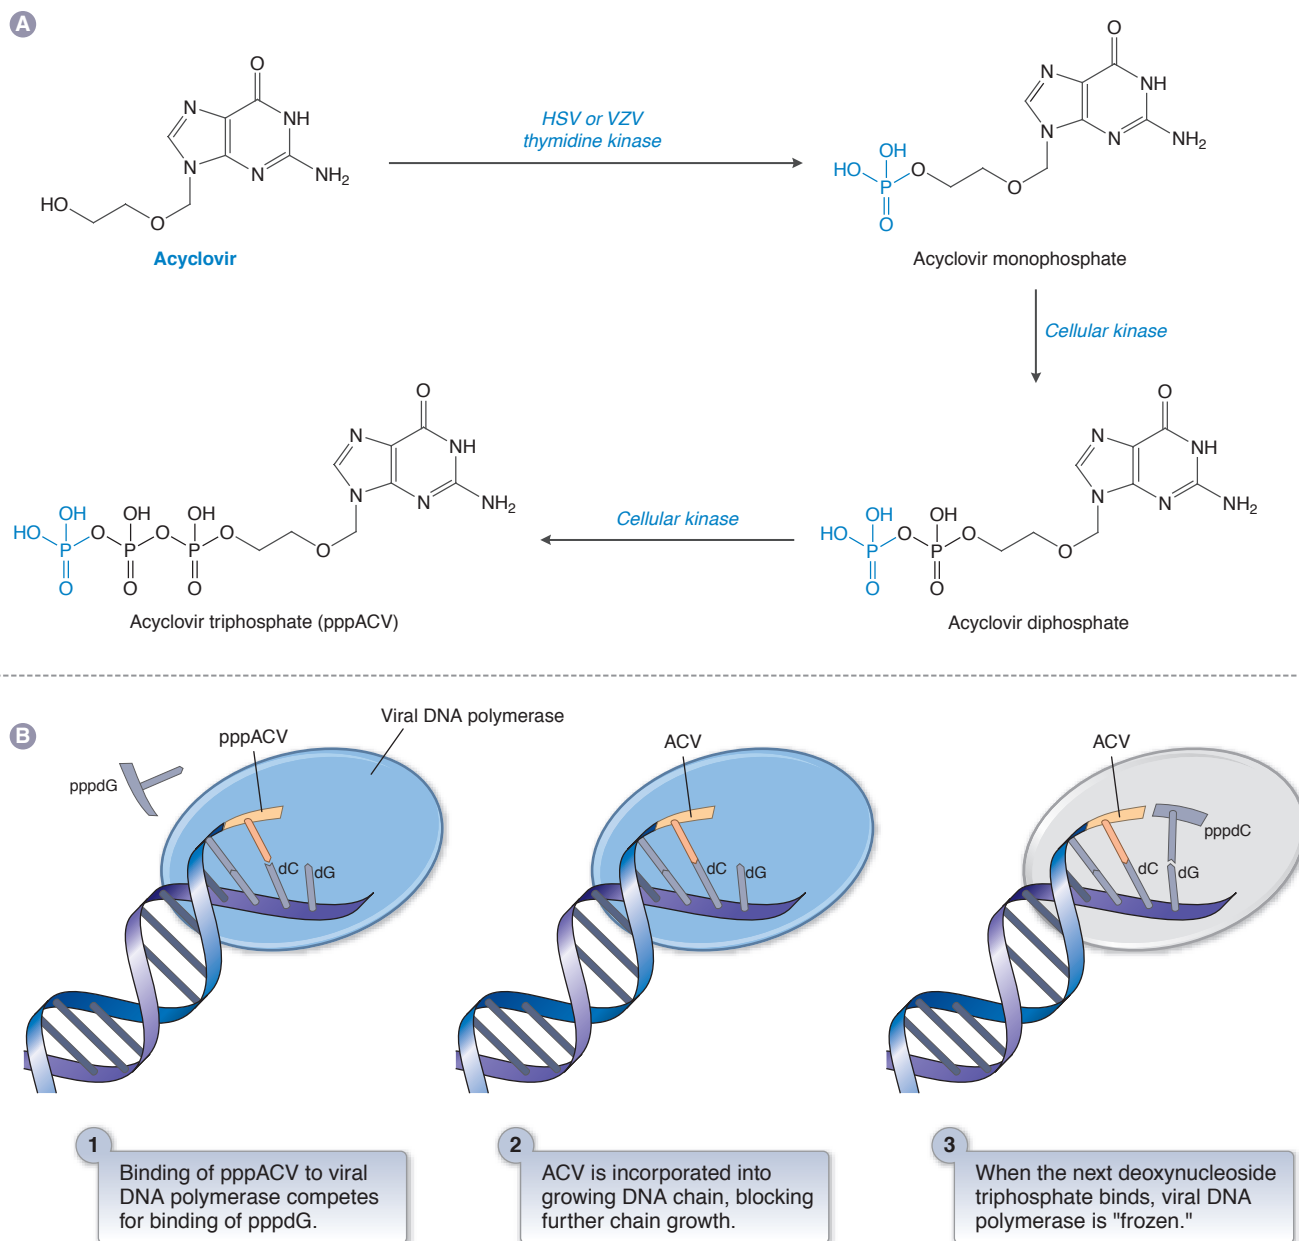

FIGURE 13.7. Mechanism of action of acyclovir (ACV). **A:** ACV is selectively phosphorylated by herpes simplex virus (HSV) or varicella zoster virus (VZV) thymidine kinase to generate ACV monophosphate. Host cellular enzymes then sequentially phosphorylate the drug monophosphate to the diphosphate and triphosphate (pppACV) forms. **B:** ACV triphosphate has a three-step mechanism of inhibition of herpesvirus DNA polymerase *in vitro*: (1) The drug triphosphate acts as a competitive inhibitor of deoxyguanosine triphosphate (dGTP) (pppdG) binding; (2) the drug triphosphate acts as a substrate and is incorporated into the growing DNA chain across from dC in the template, terminating elongation; and (3) the polymerase becomes trapped on the ACV-terminated DNA chain when the deoxynucleotide triphosphate (dNTP) binds (here shown as pppdC, dCTP, which would be templated by dG). (From Yeh RW, Coen DM. Pharmacology of viral infections. In: Golan DE, Tashjian AH, Jr., Armstrong EJ, et al., eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. Third edition. Philadelphia: Lippincott Williams & Wilkins, 2012:649–673.)

triphosphate is both a selective competitive inhibitor and substrate for viral DNA polymerase.^{21,115,233,235,303,339} Unlike ACV triphosphate, ganciclovir triphosphate is not an obligate chain terminator. Nevertheless, after incorporating ganciclovir monophosphate, HCMV DNA polymerase can stall after incorporating one additional nucleotide.³⁰³ However, biochemical and genetic studies indicate that selectivity at

the phosphorylation step and the DNA polymerase inhibition step for HCMV are not as great as the selectivity of ACV against HSV. Accordingly, the drug is more toxic than ACV. Toxicity is most commonly manifested in patients as bone marrow suppression, especially neutropenia.²⁶⁷

Most ganciclovir-resistant mutants contain *UL97* mutations, but these have a limited distribution in the gene.^{11,118}

Unlike HSV TK, HCMV UL97 protein kinase is very important for viral replication (i.e., null mutants are much less fit²⁹⁶). It seems likely that clinical *UL97* drug-resistance mutations would affect recognition of ganciclovir without gravely compromising activity on the physiologic protein substrates of *UL97* such as retinoblastoma protein and lamin A.^{135,169,185} However, this has not yet been demonstrated. Numerous different *pol* mutations have been shown to confer ganciclovir resistance (reviewed in 11 and 118). Interestingly, some lie in or near regions not altered in ACV-resistant HSV mutants, but in regions that are thought to be important for 3' to 5' exonuclease activity. How these mutations confer ganciclovir resistance is not yet known.

Cidofovir and Other Nucleotide Analogs

Cidofovir, a phosphonate-containing acyclic cytosine analog, is approved for use against HCMV, and represents a variation on the mechanism of action of nucleoside analogs. Cidofovir, with its phosphonate group, is a nucleotide analog that mimics deoxycytidine monophosphate (dCMP) (see Fig. 13.6). This charged moiety likely accounts for the relatively poor uptake of cidofovir into cells,¹⁶¹ and poor oral bioavailability. Once inside the cell, cidofovir is metabolized via cellular enzymes to its monophosphate (akin to a diphosphate) and diphosphate (akin to a triphosphate), and to a third phosphorylated form that contains a choline adduct.^{52,161} These phosphorylated forms have very long intracellular half-lives, which may be due in part to the choline metabolite serving as a reservoir.^{1,161} This property contributes to the prolonged antiviral activity of cidofovir,²⁶⁰ which provides the therapeutic advantage of infrequent dosing. In addition, because cidofovir uses cellular kinases for its phosphorylation, it is active against *UL97* mutants that are resistant to ganciclovir,²²⁵ although this also removes the selectivity gained by requiring a viral kinase for efficient phosphorylation.

The diphosphorylated form of cidofovir is an analog of dCTP that inhibits HCMV DNA polymerase more potently than it does various cellular DNA polymerases.^{48,161,394} It is also incorporated into DNA, which slows elongation, but does not result in chain termination unless two cidofovir residues are incorporated in a row.^{393,394} Many of the *pol* mutations that confer resistance to ganciclovir confer resistance to cidofovir.

Two related phosphonate-containing drugs are the acyclic deoxyadenosine monophosphate analogues, tenofovir, which is used against HIV and HBV, and adefovir, which has been used against HBV (see Fig. 13.6). The mechanisms of action of these drugs against their respective viruses are similar to those of cidofovir against HCMV, except that these drugs are chain-terminators of DNA synthesis. (See below for discussions of nucleoside analogs active against HIV and HBV.) These two drugs are administered as orally available prodrugs (Fig. 13.6). In contrast, there is currently no such approved prodrug for cidofovir, which must be administered intravenously. Orally available prodrugs of cidovir are being developed with the added potential benefit of activity against poxviruses, adenoviruses, polyomaviruses, and papillomaviruses¹⁶⁶ (e-Table 13.1).

Nonnucleoside Inhibitors of Herpesvirus DNA Polymerase: Foscarnet

As described above, nucleoside analogs can inhibit cellular as well as viral enzymes, and viruses can mutate to resist these

drugs. As a result, efforts have been made to discover compounds that might inhibit viral polymerases by other mechanisms. The first of these to be approved for clinical use was foscarnet (phosphonoformic acid, PFA; structure in Fig. 13.8). Although it is not orally available so that intravenous administration is required, and it is nephrotoxic, it is approved for treatment of severe HSV, VZV, and HCMV infections that are resistant to front-line drugs.

Foscarnet is an analog of pyrophosphate, which is a product of polymerization of nucleic acids. Unlike the nucleoside analogs described above, it does not require activation by either cell or viral enzymes but rather inhibits HCMV DNA polymerase directly and selectively. Inhibition is not competitive with deoxynucleoside triphosphates. Rather, it appears that foscarnet acts as a product analog, preventing normal pyrophosphate release so the polymerase cannot complete the catalytic cycle.^{93,271} The structure of foscarnet bound to a DNA polymerase that is a chimera of a bacteriophage DNA polymerase and segments of HCMV polymerase that are important for foscarnet sensitivity has been solved.³⁹⁸ In the structure, the drug binds to highly conserved basic residues in a closed form of the enzyme that has not translocated to the next base on the template. The drug occupies the position of the beta and gamma phosphates of an incoming dNTP. The structure suggests that foscarnet stabilizes this untranslocated state, thus stalling the polymerase.

Because foscarnet is not a nucleoside analog, HSV *tk* mutants and HCMV *UL97* mutants are not resistant to it. However, although foscarnet inhibits DNA polymerase by a mechanism that differs substantially from the nucleoside analogs, many *pol* mutants that are resistant to nucleoside analogs are resistant to foscarnet. Moreover, most foscarnet-resistant mutants are resistant to one or more nucleoside analogs (reviewed in 118). Therefore, there are patients with serious herpesvirus infections for whom there are no viable treatment options. This should be an impetus to further drug development.

Anti-HIV and HBV Polymerase Inhibitors

The retrovirus HIV and the hepadnavirus hepatitis B virus (HBV) replicate their genomes through DNA and RNA intermediates, respectively, using a DNA polymerase that can copy RNA. The HIV RT and the HBV DNA polymerase are thus essential for viral replication, and differ substantially from cellular polymerases, making them excellent targets for antivirals. The success of anti-herpesvirus nucleoside analogs provided a rationale for the development of nucleoside analogs active against HIV. Within 2 years of the identification of HIV as the etiologic agent of AIDS, a nucleoside analog, zidovudine (AZT), was shown to have antiviral activity in patients.³⁹⁵ Shortly thereafter AZT therapy was shown to have an impact on mortality in the short term.¹⁰⁰ The success of AZT, but also its limitations, led to the development of other anti-HIV nucleoside analogs. These, in turn, provided an impetus for the development of nucleoside analogs against HBV, and, with the RT validated as a target, the nonnucleoside reverse transcriptase inhibitors (NNRTIs) against HIV.

Numerous nucleoside analogs have been approved to treat HIV (see Fig. 13.6). Many of the principles that govern their mechanisms of action and resistance are similar to those of the anti-herpesvirus nucleoside analogs. For the sake of brevity, this chapter focuses on only two anti-HIV nucleoside analogs,

FIGURE 13.8. Nonnucleoside DNA polymerase inhibitors (foscarnet and nonnucleoside reverse transcriptase inhibitors [NNRTIs]). Foscarnet is a pyrophosphate analog that inhibits viral polymerases. It is approved for treatment of herpes simplex virus (HSV) and human cytomegalovirus (HCMV) infections that are resistant to other drugs. Nevirapine, delavirdine, efavirenz, etravirine, and rilpivirine, which do not mimic any known ligands of DNA polymerases, inhibit HIV-1 reverse transcriptase and are approved for treatment of HIV-1 in combination with other drugs. (Modified from Yeh RW, Coen DM. Pharmacology of viral infections. In: Golan DE, Tashjian AH, Jr., Armstrong EJ, et al., eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. Third edition. Philadelphia: Lippincott Williams & Wilkins, 2012:649–673.)

zidovudine and lamivudine (which also is an anti-HBV drug), and compares and contrasts their mechanisms with each other and with the anti-herpesvirus drugs.

Zidovudine (AZT)

Zidovudine (azidothymidine, AZT) was synthesized years before the AIDS epidemic as a potential anticancer drug. It was first reported to have anti-HIV activity in 1985.²⁵⁵ Like the anti-herpesvirus drugs described earlier, AZT is a nucleoside analog with an altered sugar moiety. In this case, it is a thymine base attached to a sugar in which the normal 3' hydroxyl has

been replaced by an azido group (see Fig. 13.6). Indeed, all of the currently approved anti-HIV nucleoside analogs lack a 3'-hydroxyl or its equivalent. (This contrasts with penciclovir and ganciclovir.)

Unlike herpesviruses, HIV does not encode kinases that can phosphorylate nucleoside analogs. AZT is an excellent substrate for cellular thymidine kinase, which phosphorylates AZT to AZT-monophosphate.¹⁰⁷ AZT-monophosphate is then converted to the diphosphate form by cellular thymidylate kinase and to the triphosphate form by cellular nucleoside diphosphate kinase.¹⁰⁷ Therefore, unlike ACV and ganciclovir,

FIGURE 13.9. Locations of drug-resistance alterations in the human immunodeficiency virus type 1 (HIV-1) and hepatitis B virus (HBV) polymerases. The HIV-1 reverse transcriptase (RT) (**top**) and the HBV DNA polymerase (**bottom**) are related enzymes with sequence and predicted structural homology, and are cartooned as bars. The HBV enzyme has a segment that is unrelated to the HIV enzyme, which is depicted here as looping out. The positions of selected substitutions and insertions that confer drug resistance are indicated in single letter code with the wild-type residue above the bar, the residue number within the bar, and mutant residues or inserts below the bar. Methionine 184 in HIV RT and methionine 204 in HBV polymerase are embedded within a YMDD motif (green) that is important for polymerase catalysis. Alterations in this methionine confer resistance to 3TC and related L-stereoisomer drugs, as does alteration of alanine 181 in HBV polymerase (also green). Boldfaced residues in HIV RT indicate the positions of thymidine analog-associated mutations that affect susceptibility to all anti-HIV nucleoside analogues. An insertion at residue 69 in HIV RT (blue) together with other alterations including M41L, K70R, L210W, T215Y, and K219Q also affect susceptibility to these drugs. Substitution of arginine for lysine 65 (purple) in HIV RT confers resistance to all nucleoside analogs except zidovudine (AZT). Substitutions of lysine 103 and tyrosine 181 (*italics*) confer resistance to nonnucleoside reverse transcriptase inhibitors (NNRTIs). Alterations of isoleucine 169, threonine 184, serine 202, or methionine 250 (red), together with a leucine-to-methionine substitution at residue 180 (orange) plus a methionine 204 substitution in HBV polymerase can result in entecavir resistance. A threonine for asparagine 236 substitution in HBV polymerase (blue) can result in resistance to adefovir (high-level) and tenofovir (intermediate).

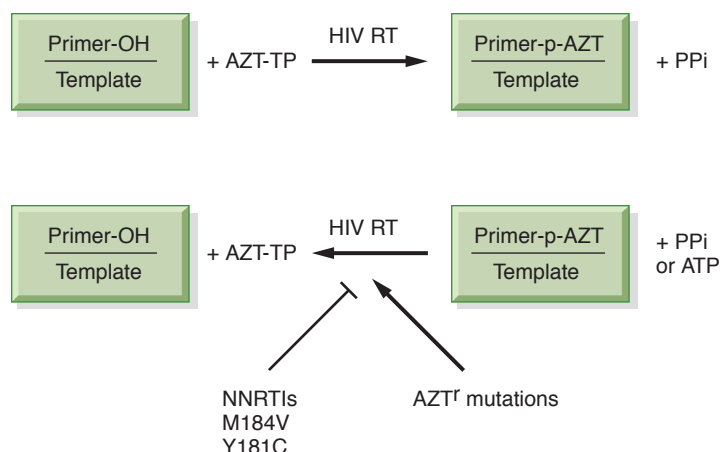

FIGURE 13.10. Biochemical mechanism of resistance to zidovudine (AZT). During synthesis of human immunodeficiency virus (HIV) DNA by HIV reverse transcriptase (RT), AZT-TP (triphosphate) is incorporated into the growing primer strand (Primer-p-AZT), generating pyrophosphate (PPi). This reaction is reversible, so that RT can excise AZT-MP (monophosphate) from the primer terminus and combine it with PPi, regenerating AZT-TP and primer/template. ATP can substitute for PPi in this excision reaction by donating two phosphates to AZT-MP. The excision reaction is enhanced by AZT-resistance mutations, but impaired by NNRTIs and certain HIV RT substitutions that confer resistance to 3TC (e.g., M184V) and NNRTIs (e.g., Y181C).

AZT-resistant mutants appear to be modestly less fit than wild-type virus.^{77,120,121,138,217}

The mechanism of AZT resistance remained elusive for over a decade. In 1998, two sets of investigators explained the mystery.^{5,249} Chain elongation by 3'-5' phosphodiester bond formation with an incoming dNTP is a reversible process. In the presence of pyrophosphate or ATP, RT can catalytically excise the terminal nucleotide by a process termed pyrophosphorolysis (Fig. 13.10). Given the K_m 's of pyrophosphate and ATP for this reaction, and the concentrations of these species in cells, ATP is the likely substrate *in vivo*. The viral DNA chain is now free to resume elongation with the removal of the chain terminating nucleoside analog. AZT-resistance mutations facilitate this reverse reaction of excision repair.^{210,250} Modeling of HIV RT (based on crystal structure) with an AZT-terminated primer/template suggests that the incorporated AZT residue would occupy the site normally used by the next incoming dNTP, and that AZT-resistance mutations, particularly those affecting codon 215, enhance binding of ATP.²⁵

AZT-resistance mutations are also selected by another thymidine analog, stavudine (d4T) (see Fig. 13.6), which has led them to be called *thymidine-associated mutations* (TAMS) (see Fig. 13.9). However, the resistance mechanism of excision repair actually applies to most, if not all, anti-HIV nucleoside analogs, with AZT-terminated primer being the most readily excised by this mechanism.³⁷⁶ Therefore, these mutations have also been termed *nucleoside-associated mutations* (NAMS). The excision repair mechanism accounts for many examples of cross-resistance of HIV toward various nucleoside analogs. Regardless of mechanism, various combinations of mutations affecting HIV RT can confer resistance to every approved nucleoside analog (see Fig. 13.9).¹⁸¹

The limited clinical effectiveness of AZT and problems with toxicity and resistance led to the development of other anti-HIV drugs and the use of combination chemotherapy.

Lamivudine (3TC)

Lamivudine (3TC) was reported to exhibit anti-HIV activity in 1992.^{54,55,329} Lamivudine and its close relative emtricitabine (FTC) appear to exhibit the least toxicity of the anti-HIV nucleoside analogs. This seems to be related to their highly unusual structures: They have an unusual sugar moiety that contains a sulfur atom and is an L-stereoisomer, not the standard D-stereoisomer of normal nucleosides (see Fig. 13.6). Lamivudine is sequentially

phosphorylated by cellular enzymes to its triphosphate.³⁷ Like AZT-triphosphate, 3TC-triphosphate is both a competitive inhibitor and a substrate for RT, and once incorporated, is an obligate chain-terminator of DNA synthesis. It is a more potent inhibitor of HIV RT than cellular polymerases.¹³⁹ The lack of toxicity of 3TC may be due to the negligible inhibition of host polymerases including mitochondrial DNA polymerase by 3TC-triphosphate.¹³⁹

High-level resistance to 3TC develops rapidly both in cell culture and in patients treated with this drug alone (reviewed in 79). A single mutation at codon 184 from Met to Val (M184V) or to Ile (M184I) confers a high degree of resistance to 3TC. M184 is within the conserved YMDD motif, in which the two Asp (D) residues are involved in catalysis of polymerization (see Fig. 13.9). M184I is less fit than M184V, which likely explains the dominance of the M184V mutant in 3TC-treated patients. Nevertheless, the M184V mutant is also less fit than wild-type virus, which may be due to decreased processivity, primer use, or initiation by the mutant enzyme or some combination of these (reviewed in 79). The crystal structure of a 3TC-resistant RT was used to develop a molecular model that posits that codon 184 mutations result in steric hindrance that obstruct incorporation of 3TC-triphosphate, but not normal nucleotides.³²⁰

The M184V mutation also has a number of other interesting effects, including conferring low level resistance to some (e.g. abacavir; see Fig. 13.6) or hypersensitivity to other nucleoside analogs (e.g. AZT and tenofovir; reviewed in 79). This hypersensitivity to AZT and other drugs in the absence of other mutations is also observed in the presence of known drug resistance mutations such that levels of resistance are reduced with the addition of M184V. This phenotypic suppression is best explained by the M184V mutation reducing the excision repair of AZT-terminated primers (Fig. 13.10).⁷⁹ Nevertheless, an accumulation of multiple mutations can result in high level resistance to both AZT and 3TC, and other single mutations such as K65R can confer resistance to 3TC (and most other nucleoside analogs) (see Fig. 13.9).²⁵¹

The mechanisms of action and resistance of FTC are very similar to those of 3TC; however, it may be slightly more potent and have a longer intracellular half-life.³⁰⁷ Its co-formulation with tenofovir has made this combination the nucleoside analog backbone of combination antiretroviral therapy.

Anti-HBV Drugs

Five nucleoside analogs—lamivudine (3TC) and tenofovir (both also approved for use against HIV), adefovir, telbivudine, and entecavir (see Fig. 13.6)—have been approved for the treatment of HBV. The structures of lamivudine, tenofovir, and adefovir were described above. Telbivudine is simply L-thymidine (see Fig. 13.6), thus sharing this isomeric configuration with 3TC and FTC. Entecavir is an unusual deoxyguanosine nucleoside analog in which the ether oxygen of the sugar is replaced with an exo carbon-carbon double bond (see Fig. 13.6). The mechanisms of action of anti-HBV nucleoside analogs are very similar to those of anti-HIV nucleoside analogs: They are converted to triphosphates by cellular enzymes, and the triphosphates inhibit HBV DNA polymerase (which is also a reverse transcriptase). All are incorporated into the growing DNA chain and cause chain termination, even those that are not obligate chain-terminators. Of note, entecavir-triphosphate has a higher affinity for HBV polymerase than does dGTP.³³¹

The similarities in mechanisms of action of these drugs against the two viruses extend to some similarities in mechanisms of resistance, but there are also important differences.²²³ For example, a mutation in the methionine codon in the HBV *pol* gene that corresponds to codon M184 in the HIV *pol* gene can confer high-level resistance to 3TC and telbivudine (see Fig. 13.9); however, in this case, the methionine to isoleucine mutant retains fitness, whereas methionine to valine or serine substitutions are usually only found in the presence of additional mutations. There is little if any evidence for HBV drug-resistance mutations resulting in increased excision of incorporated drug as do AZT-resistance mutations of HIV; rather the mutations appear to affect incorporation of drug-triphosphate by various mechanisms. Interestingly, drug resistance that requires only a single mutation develops relatively quickly, but still more slowly *in vivo* with HBV than with HIV. In at least some cases, this may be because sites of mutation also encode residues in an overlapping reading frame that affect HBV surface antigen.

As is the case with AZT resistance, multiple mutations are required to confer high level resistance to entecavir, and some of these mutations confer little resistance on their own.²²³ This correlates with slow development of resistance *in vivo*. The greater potency and slower rates of resistance to entecavir and tenofovir has led to these drugs becoming preferred for treatment of HBV.²²³ FTC and tenofovir are often used in patients who are infected with both HIV and HBV, because they are active against both viruses (even though FTC is not currently FDA approved for treating HBV infections).

Anti-HIV Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)

Five NNRTIs—efavirenz, nevirapine, delavirdine, etravirine and, in 2011, rilpivirine (see Fig. 13.8)—have been approved by the FDA for treatment of HIV infections. The first NNRTIs were discovered using high-throughput screening for inhibition of HIV-1 RT (e.g. nevirapine²⁴⁶). Candidate compounds were tested for specificity in a counterscreen by checking their ability to inhibit an unrelated polymerase. The compounds that emerged were then chemically modified to improve their antiviral activities, stabilities, and pharmacokinetics, and to reduce their toxicities. The NNRTIs are highly specific, inhibiting HIV-1 RT at low concentrations while not inhibiting

human DNA polymerases or even the RT of the closely related virus HIV-2.²⁴⁶ This biochemical selectivity is reflected by the high level resistance conferred by HIV-1 *pol* mutations.³⁰⁵ These drugs directly inhibit RT. The NNRTIs do not mimic a natural ligand of a polymerase. Each NNRTI appears to share a polycyclic structure that tends to form a “butterfly wings” conformation upon binding to RT. NNRTIs bind to a pocket near the catalytic Asp residues of RT.¹⁹³ This pocket is not observed in structures of RT in the absence of drug, but rather is stabilized by drug binding.³¹⁴ Therefore, NNRTI binding causes a substantial conformational change in RT, including distortion of the catalytic Asp residues, and slows the enzyme’s incorporation of dNTPs into DNA.^{313,338} NNRTIs inhibit pyrophosphorolysis and the excision of AZT from primer termini by RT (see Fig. 13.10;²⁶⁹), which likely accounts for synergy of these drugs against HIV.³⁰⁴

As with 3TC, resistance to NNRTIs develops quickly both *in vitro* and in patients, with single amino acid substitutions conferring high-level resistance.^{243,305,310} Common resistance mutations arise in codon 181 (see Fig. 13.9), changing Tyr to Cys (Y181C) or to Ile (Y181I), and cause high-level resistance.^{243,305} This change alters a residue known to interact with NNRTIs,^{62,193,392} and thus reduces drug binding. The Y181C mutant is relatively fit in infected cells,^{63,173} and in patients. Some but not all other NNRTI-resistant mutants exhibit reduced fitness in cells and in patients.²¹⁷ The Y181C mutation, like the M184V mutation, sensitizes otherwise AZT-resistant mutants to AZT due to suppression of excision repair (see Fig. 13.10;³³²).

The different mechanisms of action and resistance of the anti-HIV nucleoside analogs and NNRTIs help provide the rationales for various combinations of these drugs in treating HIV (see section on HIV therapies).

Ribavirin, a Nucleoside Analog Active Against RNA Viruses

Ribavirin (see Fig. 13.6) is a nucleoside analog that has been touted as a “broad spectrum antiviral”.³⁴⁸ Indeed it exhibits activity against many viruses *in vitro* and efficacy against certain RNA viruses *in vivo*. In patients, however, it has been approved only as monotherapy for severe respiratory syncytial virus (RSV) infections, and in combination with IFNs for chronic HCV infections (see below for discussion of IFNs). Ribavirin monotherapy results in little reduction in HCV levels in plasma,⁷⁸ but when added to IFNs, substantially increases the success rate of therapy.²⁹³

Structurally, ribavirin differs from the other nucleoside analogs discussed thus far, in that it has a normal sugar moiety (ribose) attached to a base-like moiety, which most resembles a purine (see Fig. 13.6). Its mechanism of action is still not well understood, especially for HCV. Ribavirin is converted to a monophosphate by cellular adenosine kinase and is known to inhibit cellular inosine monophosphate dehydrogenase (IMPDH), thereby lowering GTP pools.³⁴⁸ This could, in principle, confer selective antiviral activity if certain viral functions have higher K_m values for GTP than do most cellular enzymes. Inhibitor and RNA interference experiments suggest that IMPDH inhibition could be important for the anti-HCV activity of ribavirin.^{261,405} A second possible selective mechanism for ribavirin action could be inhibition of viral RNA polymerase. A related possible mechanism, called “error catastrophe,”

is that ribavirin incorporation by viral RNA polymerase increases the already high mutation rate of the virus⁸⁷ “over the edge” of an “error threshold” so that few or no functional viral genomes are produced. This has been investigated most thoroughly with poliovirus,^{72,73,284} but similar studies have been performed with HCV.^{68,198,226,405} This is an appealing concept, but remains unproven, particularly for RSV and HCV. In HCV replicons, ribavirin resistance was found to be due to mutations affecting the NS5A protein rather than polymerase,²⁸⁵ and studies of viral mutagenesis in patients treated with ribavirin have not provided definitive answers.^{227,281} A fourth possible mechanism is that ribavirin induces IFN-stimulated genes, which may be particularly relevant to the use of ribavirin in combination with IFNs.^{96,361} A fifth possible mechanism involves stimulatory effects on T helper cell 1 responses involved in clearing virus from the liver.¹⁶² If anything, there is even less known about the mechanism of ribavirin action against RSV. Further investigations of the mechanisms of ribavirin action and resistance may yield interesting new insights into virus biology and biochemistry.

New nucleoside analog and nonnucleoside inhibitors of viral polymerases are being developed. For example, as of late 2012, several such inhibitors of HCV RNA polymerase were in phase II clinical trials (e-Table 13.1). Therefore, this area of antiviral agents remains highly active.

Anti-Human Immunodeficiency Virus Integrase Inhibitors

A crucial stage in the replication of HIV and other retroviruses is integration of the linear, dsDNA product of reverse transcription into the host genome. The protein that carries out this step, integrase, is an essential enzyme. Integrase assembles onto sequences from the ends of HIV DNA, cleaves dinucleotides from each 3' strand, and transfers these strands to covalently link them with target DNA (Fig. 13.11). The catalytic core of integrase includes three conserved acidic residues called the DDE motif (Fig. 13.11), which binds Mg^{2+} that is essential for integrase activity. Efforts to identify specific inhibitors of HIV integrase that could serve as effective antiviral drugs commenced in the early 1990s. A breakthrough came when Daria Hazuda and her colleagues at Merck developed an assay selective for DNA strand transfer.¹⁵¹ Using this assay, they identified integrase inhibitors that act much more potently at this step than at prior steps (Fig. 13.11). These inhibitors contained a diketoacid moiety, which binds to the metal coordinated by the DDE motif, and additional moieties that bind to the enzyme. Medicinal chemistry studies of various classes of diketoacid scaffolds led to the development of raltegravir (Fig. 13.11).³⁵¹ Raltegravir was tested against a variety of enzymes that are Mg^{2+} -dependent (e.g., HIV RT), and was highly selective for integrase. Its selectivity for the strand-transfer step seems to depend on binding to a conformation of integrase that is stable only after processing of 3' ends. Indeed, viral DNA may form part of the binding site for the drug.^{2,45,238}

Raltegravir inhibits HIV replication at low nanomolar concentrations. As expected, HIV mutants resistant to raltegravir contain mutations in sequences encoding the integrase, with most mutations that confer resistance altering residues close to the inhibitor binding site.²³⁸ Of mechanistic interest, one mutation alters a residue that, in the crystal structure, makes contact with a nucleotide corresponding to the 5' terminus of

viral DNA. There are also mutations that do not themselves confer resistance, but increase the effects of other mutations. Similar mutations are selected by raltegravir in cell culture and in patients. Single mutations seem to be sufficient to confer clinically significant resistance, but most of these mutations decrease HIV fitness at least modestly.²³⁸

In 2012 elvitegravir, another integrase inhibitor, was approved, and dolutegravir, which is active against many raltegravir-resistant mutants, was in late-stage clinical trials. It seems likely that this class of drugs will become increasingly important for HIV therapy.

Inhibition of Viral Assembly and Maturation Protease Inhibitors

Virus assembly and subsequent events to form an infectious virion are attractive targets for drug discovery because they are unique to virus biology. For many viruses, including HIV, mere assembly of proteins and nucleic acid into particles is not sufficient to produce an infectious virion. For such viruses, an additional step—maturation—is required. In most cases, these viruses encode proteases that are essential for maturation. The approved antiviral drugs that target HIV protease are saquinavir, ritonavir (which is now used mainly at low dose to boost plasma drug levels of other protease inhibitors), lopinavir, amprenavir and its prodrug fosamprenavir, indinavir, nelfinavir, atazanavir, darunavir, and tipranavir (Fig. 13.12).

Several features gleaned from a variety of studies established HIV protease as an attractive target for drug discovery and design. Molecular genetic studies showed that the protease is essential for HIV replication, and that a point mutation is sufficient to inactivate the enzyme and viral infectivity, suggesting that a small molecule could be effective.¹⁹² The cleavage sites in the viral polypeptide substrates of HIV protease are conserved and somewhat unusual, suggesting both specificity and a starting point for drug design.^{283,292} Unlike the human proteases most closely related to it, HIV protease is a symmetric homodimer, and each subunit contributes to the active site, again suggesting both specificity and a starting point for drug design.²⁶⁵ The enzyme can be easily overexpressed and assayed, and its crystal structure has been solved,^{263,389} all aiding drug discovery.

The HIV protease inhibitors are paradigms of rational drug design. For simplicity, only the development of ritonavir will be detailed. Ritonavir and the other protease inhibitors are peptidomimetics. Indeed, all but tipranavir retain peptide bonds. Ritonavir's design began with the recognition that a natural substrate of the protease contains a phenylalanine-proline (Phe-Pro) bond; mammalian enzymes rarely if ever cleave at such a site. The transition state of this substrate during cleavage was then modeled (Fig. 13.13, top). Knowing that HIV protease is a symmetric dimer, an analog of the transition state was modeled, using the same residue, phenylalanine, on both sides, and with a CHOH group that mimics the transition state as the center of symmetry. This molecule, A-74702, was a very weak inhibitor of HIV protease, but adding groups symmetrically to both ends to form A-74704, resulted in a greater than 40,000-fold increase in potency ($K_i \sim 5$ nM).⁹²

Attempts to modify A-74704 to improve solubility reduced potency, so a related potent inhibitor, A-75925, in which the center of symmetry was a C-C bond between two CHOH groups, became the scaffold for further additions to both ends.¹⁹⁰ This resulted in a soluble, highly potent inhibitor,

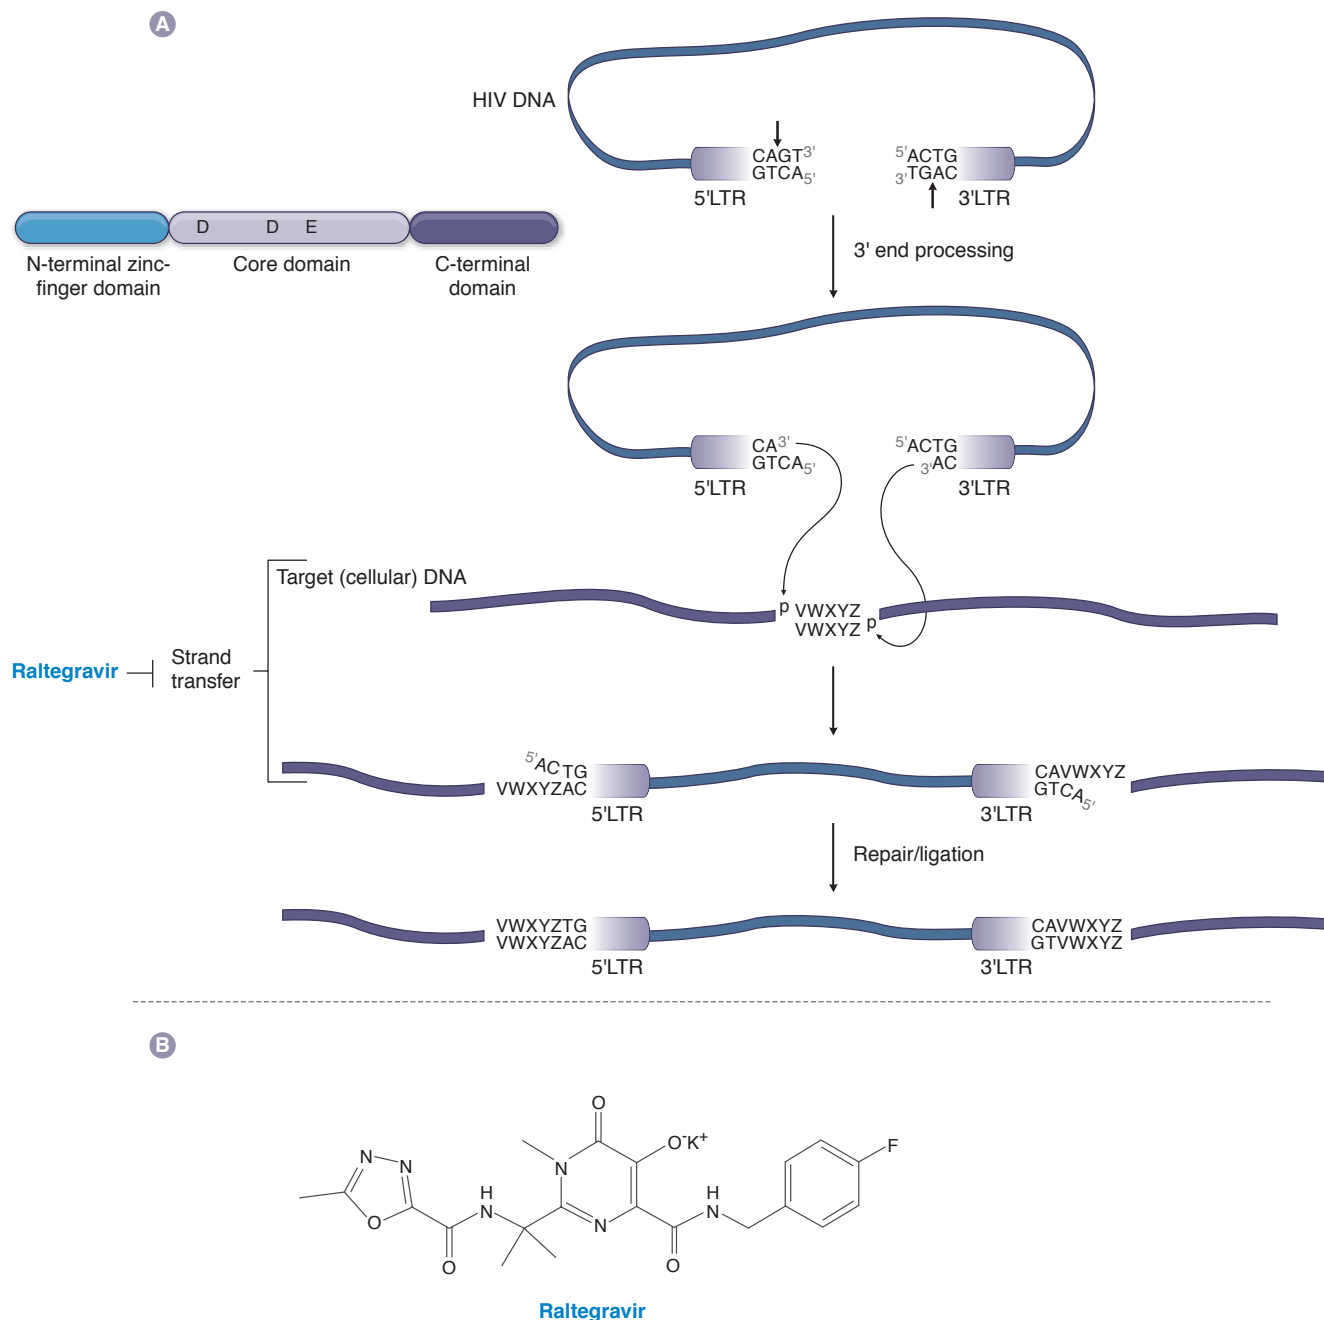

FIGURE 13.11. Human immunodeficiency virus (HIV) integrase and raltegravir action. A: Linear, double-stranded HIV DNA, generated by reverse transcription, contains a four-base sequence at each of its ends, as part of its long terminal repeat (LTR). Integrase (IN), which contains an N-terminal zinc-finger domain important for DNA binding, a C-terminal domain, and an internal core domain containing three acidic residues (DDE) that coordinate magnesium ions important for catalysis, binds to HIV DNA (as part of a larger complex) and cleaves a dinucleotide from the 3' strand at each end of viral DNA (3' end processing). The integrase-viral DNA complex then catalyzes the attack of the recessed 3' ends of viral DNA on phosphodiester bonds of target (cellular DNA) (strand transfer). The product results in 5' flaps of viral DNA and gaps in cellular DNA. Integrase releases, and host enzymes remove the flaps and repair the gaps, resulting in integrated viral DNA flanked by duplicated host sequences. Raltegravir inhibits the strand transfer step of this process. (Modified from Yeh RW, Coen DM. Pharmacology of viral infections. FIGURE 13.13. Steps in the development of ritonavir. **A:** On the left is shown a substrate sequence that is cleaved by human immunodeficiency virus (HIV) protease between a phenylalanine (phe) on the N-terminal side of the cleavage (P_1) and a proline (pro) on the C-terminal side (P_1'). On the right, the transition state of this sequence during protease cleavage is modeled. The transition state contains a rotational axis of symmetry **B:** Structure-based development of ritonavir began with A-74072 (**top left**) that mimics the transition state with a single CHOH moiety between two phenylalanines (to maximize symmetry). This compound, which had weak inhibitory activity, was modified by symmetric addition of other groups to yield A-74074, which was more potent (CBZ, carboxybenzyl), but was insufficiently soluble. This was modified to mimic the transition state with CHOH groups on each side of the axis of symmetry (A-75925, **top right**). This was also poorly soluble, but could be improved by adding more groups (A-77003, **middle**). That compound was not very orally available, so additional modifications, including the removal of a central OH group, were made, resulting in ritonavir (**bottom**). The choices of modifications were aided by crystal structures of intermediate compounds bound to HIV-1 protease. For each compound, the inhibitory potencies against HIV-1 protease *in vitro* (IC_{50}) and against HIV in infected cells (antiviral activity) are provided.

A-77003 (Fig. 13.13, bottom). However, this compound was not absorbed orally.¹⁸⁹ It was modified by removing a central OH group and altering other moieties at each end (Fig. 13.13, bottom). This resulted in less solubility, but improved antiviral activity and good oral bioavailability.¹⁸⁸ These improvements took advantage of the x-ray structure of HIV protease complexed with each version of the inhibitors (reviewed in **4 and 388**). By examining these structures, chemists were able to make informed guesses about what groups to add or subtract. The result was ritonavir.

Crystallographic studies reveal that upon binding of protease inhibitors, the enzyme assumes a conformation with closed “flaps” that are unable to undergo conformational changes that help form the active site (reviewed in **4 and 388**). The drugs work in cell culture as expected: HIV-infected cells exposed to protease inhibitors continue to make viral proteins, but these proteins are not processed efficiently.⁷⁰ Viral particles bud from the infected cells, but they are immature and noninfectious.¹¹⁴ Mutations conferring drug-resistance map to HIV sequences encoding the protease, confirming that protease is the target.²⁷²

Resistance to protease inhibitors has taught us a great deal about both the drugs and the virus.^{23,66,181} Mutations in more than 30 of the 99 amino acid residues of protease have been selected with the different protease inhibitors, with as many as 24 conferring resistance to any one drug. Some of the mutations affect the active site or sites known to interact with the inhibitors, and thus the mechanism of resistance can be readily understood. However, other mutations affect more distal sites, and it is not clear how they confer resistance. Resistance is often cumulative. In some patients, after failing multiple regimens containing protease inhibitors, more than 20 of these mutations have accumulated in their virus, demonstrating the remarkable plasticity of this enzyme.^{159,181} There is even an example of a virus whose replication is enhanced by subinhibitory concentrations of a protease inhibitor.²³⁷

Different protease inhibitors tend to select different mutations, at least initially. Therefore, although the drugs all work by similar mechanisms, the first mutation selected for resistance to one protease inhibitor often does not confer resistance to another. This can be understood by considering that although the different drugs tend to share similar functionalities that interact with the protease active site, each drug has a different functionality that confers high affinity binding via interactions with a particular site specific to the drug. Therefore, a single mutation that interferes with binding of one drug will not necessarily affect binding of the other. As mutations accumulate, however, cross-resistance develops among the protease inhibitors. Mutations affecting protease cleavage sites can also confer resistance.⁸⁶ These result in more easily cleaved precursor substrates for the protease. Different protease mutations also have differing effects on viral fitness. Certain mutations can be readily found in untreated patients, suggesting high fitness, whereas others are not detected except following drug treatment, and often decrease fitness. Cleavage site mutations can improve the fitness of protease mutants.^{86,230,399} These different features of resistance to protease inhibitors have important clinical implications (see section on anti-HIV therapy).

Inhibition of Viral Release: Influenza Virus Neuraminidase Inhibitors

Inhibitors of influenza virus neuraminidases block viral release of influenza A and B viruses. The rationale for their action

follows from the mechanism of viral attachment. Influenza attaches to cells via interactions between the virion hemagglutinin and sialic acid, which is present on many cellular membrane glycoproteins. However, upon egress of influenza virus from cells at the end of a round of replication, hemagglutinin on nascent virions again binds to sialic acid and tethers virions, preventing release and initiation of new rounds of infection. To overcome this problem, influenza virus encodes a virion neuraminidase, which cleaves sialic acid from the membrane glycoproteins. Studies using influenza virus mutants or an early neuraminidase inhibitor showed that without neuraminidase, the virus remains tethered and cannot spread to other cells.^{220,275,276} In 1992, structures of the neuraminidase-sialic acid cleavage product were solved.^{35,369} The structure showed that sialic acid occupied two of three well-formed pockets on the enzyme. Based largely on this structure, a new sialic acid transition state analog was designed to make energetically favorable interactions in all three of the pockets, principally by adding a guanidino group³⁷⁰ (Fig. 13.14). This compound, zanamivir, inhibits neuraminidase with a K_i of about 0.1 nM. Zanamivir is active against both influenza A and influenza B viruses with potencies of about 30 nM. However, it is not orally bioavailable, and must be administered as an aerosol.

Efforts to obtain a neuraminidase inhibitor with better pharmacokinetic properties than zanamivir resulted in oseltamivir (Fig. 13.14).^{191,211} Oseltamivir makes use of a carbocyclic ring based on a transition state analog of sialic acid. Rather than use a guanidino group to occupy a third pocket, it makes stronger contacts with one of the two pockets bound by sialic acid by adding a hydrophobic group (Fig. 13.13). Oseltamivir's high oral bioavailability depends in part on its being an ester prodrug, which when cleaved gives rise to the active carboxylate (Fig. 13.14).

Most neuraminidase resistance mutations result in an enzyme that is less inhibited by the drug.²⁴⁵ As would be expected by the differences in drug binding to the enzyme (Fig. 13.14), mutants resistant to one drug are not necessarily resistant to the other. This phenomenon gained worldwide notice when a human who became ill with virulent, avian H5N1 influenza A virus despite prophylaxis with oseltamivir was found to harbor oseltamivir-resistant, but zanamivir-sensitive virus.²²⁸ Still, compared with amantadine, for many years it was relatively difficult to generate mutants resistant to zanamivir or oseltamivir in the laboratory, and they appeared less frequently in the clinic. This was due in part to most such mutants, such as those containing the H275Y substitution that confers oseltamivir-resistance, being less fit than wild-type virus.¹⁷⁷ Indeed, the oseltamivir-resistant H5N1 just mentioned replicated less well in ferrets than did a drug sensitive virus from the same patient.²²⁸

However, during the 2007–2008 influenza season, virulent, readily transmitted H275Y viruses began to appear among seasonal H1N1 isolates, even in the absence of oseltamivir therapy.¹⁴⁶ These viruses containing Y275 appear just as fit *in vitro* as controls containing H275.^{22,298} The fitness of these H1N1 mutants can be attributed to permissive secondary mutations that allow increased expression of the H275Y mutants on the surface of the infected cell.²² As described in the Overview section of this chapter, another class of mutants resistant to the neuraminidase inhibitors contains altered hemagglutinins.

FIGURE 13.14. Structure-based design of inhibitors of influenza A and B virus neuraminidase. **A:** Shown is a model of sialic acid (space-filling structure in dark purple) bound to the influenza neuraminidase (green and light purple), with the amino acids that bind sialic acid shown in stick form. This structure was used to design transition state inhibitors that bind with higher affinity than sialic acid. **B:** Structures of sialic acid and the neuraminidase inhibitors oseltamivir and zanamivir. **C:** Diagram of the active site of influenza virus neuraminidase, showing the binding of sialic acid, zanamivir, and GS 4071 (oseltamivir is the ethyl ester of this compound), showing how the different ligands interact with pockets in the active site. Note that the compounds in **C** are flipped 180 degrees relative to how they are shown in **A** and **B**. (A and B, from Yeh RW, Coen DM. Pharmacology of viral infections. In: Golan DE, Tashjian AH, Jr., Armstrong EJ, et al., eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. Third edition. Philadelphia: Lippincott Williams & Wilkins; 2012:649–673. **C**, modified from Laver WG, Bischofberger N, Webster RG. Disarming flu viruses. *Sci Am* 1999;280:78–87.)

Other neuraminidase inhibitors are in clinical development. One of these, peramivir, is approved in Japan and Korea, but not yet in the United States (e-Table 13.1). Nevertheless, in 2009, it was authorized for emergency use in severe cases of pandemic H1N1 influenza in hospitalized patients, because it

can be administered intravenously. The H275Y mutation confers resistance to peramivir, limiting its use against oseltamivir-resistant virus.

With increasing concerns regarding influenza pandemics, the mechanisms of action and resistance of neuraminidase

inhibitors have become very important, as has the development of new anti-influenza drugs that are active against mutants resistant to neuraminidase inhibitors.

Antiviral Therapies That Target Immune Processes

Two types of drugs approved for treatment of viral infections—imiquimod and IFNs—do not inhibit virus replication directly. Rather, they enhance innate host immune responses to viral infection. Imiquimod (e-Fig. 13.1), which is approved for treating certain diseases caused by human papillomaviruses, interacts with Toll-like receptors TLR7 and TLR8 to boost innate immunity, including secretion of IFNs.^{117,155,183} Interferon alpha is approved for treating HCV; HBV; condyloma acuminata, which is caused by certain human papillomaviruses; and Kaposi's sarcoma, which is caused by Kaposi's sarcoma-associated herpesvirus (human herpesvirus 8). The actions of IFNs are reviewed in Chapter 8. However, which of the many activities induced by IFNs contribute to their therapeutic effects (e.g., against HCV; reviewed in 95) remain poorly understood. Interestingly, genetic polymorphisms in a region encoding certain type III IFNs, which are induced by IFN- α , are associated with response of HCV infections to IFN- α and ribavirin, with lower expression of these interferons associated with lower responses to therapy.^{113,352,358} Follow-up studies of this observation and greater understanding of mechanisms by which viruses inhibit interferon action (e.g., HCV; reviewed in 95) may facilitate the development of more targeted therapies.

PRINCIPLES OF ANTIVIRAL THERAPY

General Concepts

Viral Dynamics and the Role of the Immune System in Antiviral Therapy

Different viruses can have very different dynamics of infection, and these differences have major impacts on the goals and effects of antiviral therapy. Many of these differences relate to the interplay between antiviral therapy and in the immune system. Acute viral infections of immunocompetent patients are usually cleared by the immune system in a matter of days. It is not surprising then that treatment of most acute influenza virus infections in immunocompetent patients with drugs such as oseltamivir reduces the duration of fever and other symptoms by only a day or so. A corollary is that treatment must be started as soon as possible to obtain clinical benefits. Indeed, prophylaxis can be the most effective approach. Many of the same considerations apply to recurrent disease caused by reactivation of latent viral infections in immunocompetent patients. In the case of frequently recurring herpes genitalis, suppressive therapy is much more effective than treating each episode. Another issue in acute infections can be the extent to which symptoms are due to viral replication rather than the immune response to the virus. For example, most of the symptoms of mononucleosis caused by Epstein-Barr virus (EBV) infections occur when viral replication has subsided. As a result, even though several antiviral drugs that are clinically useful against other herpesviruses are potent inhibitors of EBV replication, they are ineffective at treating mononucleosis.

Many of the viruses for which antiviral drugs have been developed cause persistent infections. The primary goal in the

management of persistent viral infections with antiviral therapy is sustained suppression of viral replication. In contrast with acute infections, antiviral therapy can be effective when initiated well after symptoms have appeared. In some cases, such as HCV infections, persistent viral replication occurs in the face of an immune response that usually is incapable of clearing the virus by itself. However, HCV does not form latent infections, and thus can be cured by inhibiting viral replication. In other cases, such as reactivating HCMV in transplant patients, the immune system cannot control virus replication. Antiviral drugs cannot cure HCMV infections, but they can stave off viral disease until an effective immune response is restored. Prophylactic approaches against HCMV are used very selectively in immunosuppressed patients because of the toxicities of anti-HCMV drugs. Physicians often opt for preemptive therapy when a certain level of replicating virus is detected, but before disease symptoms are manifest.

The interplay between antiviral therapy, viral dynamics, and the immune response, and the roles of tissue compartments and cellular reservoirs has been investigated in the most detail with HIV, and is discussed below.

Interplay between Anti-HIV Therapy, Viral Dynamics, and the Immune System

The generation of virions in chronic HIV infection is enormous, and the goal of antiviral therapy is to suppress this. With the initiation of effective treatment, the clearance of virions from the plasma is rapid (minutes to hours). The clearance rate constant varies little among individuals and different stages of disease.²⁸² The steady state levels of viral nucleic acid in the blood are thus determined by the rates of virus production. For HIV these rates of production are a function of the number of infected lymphocytes in the lymphoid tissue.^{129,130} The rate of decline of CD4 lymphocytes is thus directly related to the steady state level of plasma HIV RNA. The higher the RNA levels, the faster the loss of CD4 cells, and the shorter the duration of HIV infection before death.²⁴⁴ Because the CD4 count determines the risk of disease and death, and the level of HIV RNA determines the rate of CD4 cell decline, these values have been routinely used clinically to assess clinical status and urgency to initiate therapy.³⁶²

When potent combination antiretroviral therapy is effectively administered, levels of HIV RNA in both plasma and infected cells in lymphoid tissue rapidly decrease. The rapid, first phase clearance is attributable to the death of infected, activated CD4 lymphocytes and the prevention of infection of new cells.²⁸² The second phase clearance rate is lower and more variable in slope among individuals. It has been attributed to clearance of infected macrophages or to chronically infected CD4 lymphocytes with lower rates of cell death, but may also result from the clearance of the large burden of virions bound to dendritic cells in the germinal centers of lymph nodes.^{39,280,403} Failure to reduce plasma HIV RNA levels to below the limit of detection (20–75 copies/ml with the currently available assays) indicates inadequate suppression and a risk for the outgrowth of resistant virus.³⁶² Even in patients sustaining suppression below this level for 10 years or more, very low levels of viral RNA can often be detected in tissues and blood. This low level viremia is sustained at steady state levels of less than 50 copies of HIV RNA/ml plasma as measured following ultracentrifugation and using very sensitive assays. Although ongoing

replication may be occurring in some patients, several lines of evidence would argue that activation of latently infected CD4⁺ lymphocytes or long-lived persistently infected cells like macrophages or pluripotent multiprogenitor cells are the source of this viremia. Notably, no new drug-resistance mutations emerge, no nucleotide sequence evolution can be discerned, and treatment intensification with additional potent antiretroviral drugs fails to perturb the viremia.^{242,277}

The immunologic consequences of suppressing HIV replication are dramatic. The increase in CD4 lymphocyte numbers has two phases. In the first month or two the increase is often large (20–100 cells per μ l blood).^{7,18,128} The magnitude is proportional to the steady state HIV RNA levels before treatment, which drives the level of generalized activation of the immune system. The normal distribution of lymphocytes is 2% in the circulation and 98% in the lymphoid tissues. With the immune activation of HIV infection, the distribution shifts to 1% and 99%.^{129,404} Therapy largely corrects this shift, and results in redistribution of mostly CD45RO⁺ memory T cells from the lymphoid tissue back to the circulation.^{31,274,404} Production of new cells, mostly of the CD45RA-naïve phenotype, is generated both by restored thymic mass and function, which is age related, and by peripheral proliferation.^{84,239}

The generation of cell numbers is not sufficient to account for the success of antiretroviral therapy. It is the restoration of immune function that has transformed the natural history of AIDS. Both CD4 and CD8 T-cell responses to recall antigens are regenerated.^{7,140,194} Persistent opportunistic infections are often resolved. Occasionally, subclinical chronic infections with *Mycobacterium avium complex* (MAC) or HCMV, for example, are manifested when a restored immune response produces a local inflammatory reaction. Patient care has been transformed with the ability to withdraw prophylactic or suppressive therapy for various opportunistic infections, which had previously been lifelong commitments.

The probability of success of suppressing HIV replication and of preventing the emergence of resistance (see below) is significantly impacted by the level of CD4 cells and of HIV RNA in the blood. This relationship is a practical argument to avoid treating before it is too late, but it also points out that the imperfect efficacy of drug treatments is complemented by having more immunity and less virus. It is noteworthy that the success of treatment of opportunistic infections in AIDS patients, including antiviral therapy for HSV, VZV, and HCMV infections, also is similarly affected by CD4 cell count.

Compartments and Reservoirs

Treatment of HIV is complicated by the existence of tissue compartments and cellular reservoirs. Although there is trafficking between the blood and central nervous system (CNS), much virus in the CNS evolves independently.³⁴⁶ Similar observations have been made with virus in semen.²⁸⁸ Drug penetration into these compartments differs from the circulation and lymphoid tissue, and varies with each drug. Latently infected CD4 lymphocytes represent a small fraction of infected cells during active infection, but they have long half-lives,^{97,311,345} and may be sustained for life by homeostatic proliferation of latently infected memory CD4⁺ lymphocytes.⁴⁹ Consequently, virus archived at any time during infection can reemerge and propagate after the withdrawal of therapy.

Drug Resistance in Antiviral Therapy

The speed, magnitude, and clinical impact of the emergence of resistance differ among antivirals and viruses. As summarized earlier in the chapter, the rate at which mutants that are resistant to a given drug will emerge is a function of mutation rate, target size for mutation, replication rate, preexisting size of the population, and fitness. All of these factors can have clinical impact. For example, at presentation, an HIV-infected individual contains 10^{11} virions,¹³⁰ more than 10 billion (10^{10}) HIV-1 virions are generated daily,²⁸² and on average one mutation is generated for each newly generated genome.²³² Therefore, genomes with each possible mutation, as well as many with double mutations, are likely generated daily. Moreover, during HIV infection, drug-resistant virus is readily archived in latently infected cells to confound treatment modifications for the remainder of the patient's life.^{98,390,311} Therefore, an HIV-infected individual is highly likely to develop an infection that is resistant to any given antiviral drug. In contrast, ACV resistance almost never develops during treatment of HSV or VZV in immunocompetent patients. These patients contain much less virus, and the virus replicates and mutates at a much lower rate than HIV. Nevertheless, ACV resistance does occur more often in immunocompromised patients in whom virus replicates to higher levels and more persistently.

Of particular clinical relevance to antiviral resistance are drug concentrations attained in patients that achieve therapeutic effects. In this regard, fitness is highly important. With increasing drug exposure in a patient, the selective pressure on the replicating virus population increases to promote the more rapid emergence of drug resistant mutants; that is, as drug-sensitive viruses become less fit. For example, higher doses of AZT or zidovudine monotherapy tend to select for drug-resistant HIV more readily than do lower doses.^{256,309} As drug concentrations of monotherapy increase, the likelihood that resistant mutants will arise increases, as long as significant levels of virus replication persist. This can occur through improper dosing, suboptimal adherence, pharmacologic hurdles, and ineffectively treated compartments. Incompletely suppressed viral replication with drug regimens sufficient to exert selective pressure drive the evolution and fixation of drug-resistant virus at a rate Darwin himself never imagined. This scenario may explain the emergence of an oseltamivir-resistant H5N1 influenza virus in a patient who had been given relatively low doses of drug as prophylaxis.²²⁸ With further increases in concentration of antiviral drugs, especially in combination, the amount of virus replication diminishes to the point where the likelihood of emergence of resistance begins to diminish, and becomes nil when virus replication is completely inhibited.³⁰⁶ The ultimate goal of antiviral therapy, especially for viruses like HIV, HBV, and HCV, which have high mutation rates, high replication rates, and high preexisting populations, is to apply drug regimens that completely inhibit virus replication.

Clinical Impact of Drug Resistance

It may seem obvious that drug resistance is important clinically. However, many treatment failures are not due to drug resistance, and many drug-resistant viruses do not cause treatment failures. To demonstrate thoroughly that drug resistance is clinically important, it is necessary to have evidence of treatment failure, to isolate drug-resistant virus, and to successfully

treat the disease with a second drug to which the virus is susceptible.

For acute infections like influenza, which are largely controlled by the immune system, antiviral drug resistance is generally not a major problem in the patient in whom it arises. Therefore, during monotherapy with adamantanes or neuraminidase inhibitors, variants probably emerge in all patients within a week, but in immunocompetent patients, that is when the infection has largely resolved. Transmission of resistant virus to others can occur, however, and the antiviral efficacy will be impaired in these secondary cases. In persistent infections, antiviral drug resistance can be a matter of life and death. As resistance mutations accumulate, drug susceptibility diminishes, progressively reducing the efficacy of antiviral regimens. Continued replication in the presence of drug selects for even greater levels of resistance to each administered drug and progressive cross-resistance to drugs of the same class. This drives a vicious cycle of treatment failure and yet more difficult treatment challenges. Regimens for patients who are failing treatment, while constrained to more limited options by resistance, must still contend with the same obstacles of adherence, pharmacology, and tolerability that challenged the first regimen.

Drug-resistant herpesviruses and HIV can establish latent infections. Drug-resistant HIV, HBV, and influenza A viruses have been transmitted to other individuals. In the case of HIV, resistant virus in blood or genital secretions can be transmitted during sex, needle sharing, or childbirth.²¹⁶ Rates of transmission of drug-resistant HIV appear to have increased, with 5% to 20% of primary infections caused by drug-resistant virus in developed countries.^{216,218} Such patients are more likely to fail their first treatment regimen. Resistance in developing countries has become increasingly appreciated with the rollout of treatment access.²⁹⁵

Strategies to Combat Drug Resistance

The increasing prevalence of antiviral drug resistance raises challenges to the effective treatment of individuals and to the public health similar to those that have resulted from widespread antibiotic resistance. One strategy to combat this problem is to test viruses for drug resistance before choosing antiviral regimens. Resistance testing can help determine which drugs will not work (thereby diminishing cost, toxicity, and inconvenience) and which drugs are most likely to be effective. Such testing is rapidly being incorporated into standard HIV care,¹⁶⁰ and is certain to become part of the management of HBV and HCV. These tests can be performed most rapidly if they are genotypic (i.e., detecting mutations at the level of DNA or RNA) rather than phenotypic (i.e., measuring changes in drug susceptibility). Genotypic assays are much easier to develop if only a few mutations confer clinically relevant resistance. As reviewed in the sections on mechanisms of specific antiviral drugs, this is more likely to be true for some drugs (e.g., lamivudine) than others (e.g., ACV). As numerous mutations in various combinations accumulate, as occurs during treatment of HIV with RT and protease inhibitors, the interpretation of genotypic assays can become very difficult, and phenotypic assays may be required.

A second key strategy is combination chemotherapy. This strategy combats resistance on several levels. First, the probability of a virus being resistant to multiple different drugs (with different mutations conferring resistance) is the product of the

probabilities of resistance to each drug. This makes it much less likely that a preexisting virus in the patient will be resistant to all of the drugs. Second, the combination is likely to suppress replication more completely than would any of the drugs alone. This would provide less chance for resistance to develop. Third, members of the combination might synergize, thereby providing even greater efficacy. It is crucial that drugs in the combination not antagonize each other's activities by mechanism of action or pharmacologic interaction. Fourth, a mutation conferring resistance to one drug in a combination might yield clinical advantages, for example, by making the virus less fit or by sensitizing otherwise resistant viruses to a second drug. Such advantages have been invoked for the M184V mutation in HIV and the M204V/I mutation in HBV that confer resistance to 3TC and FTC (reviewed in 79).

Why not always use combination chemotherapy? Additional drugs add costs, toxicities, and pharmacological interactions, which sometimes exacerbate those of the first drug. Combination regimens can be difficult for the patient, reducing adherence with the regimen. Sometimes too few drugs are available to combine, or if there are multiple drugs, they entail similar mechanisms of action and resistance. Drug resistance is relatively uncommon with certain virus infections, such as herpesvirus infections in the immunocompetent. These points help explain why combination chemotherapy is rarely used for treating herpesvirus or influenza virus infections.

The history and clinical practices as of 2012, and issues particular to therapies of different viruses will now be reviewed.

HIV Therapy

In the 27 years since AZT was first clinically evaluated, 25 drugs have been approved for treating HIV (Fig. 13.15). This remarkable drug development experience helped elucidate many of the principles of antiviral therapy described earlier. A review of the clinical evaluation of each of the anti-HIV drugs and each of the combinations of these drugs for patients in various stages of disease is beyond the scope of this chapter. Guidelines summarizing the practical use of currently available antiretrovirals are frequently updated.^{359,362} With the availability of these treatment alternatives and with an appreciation of the principles of antiviral therapy, HIV has been transformed into a manageable condition for most patients in the developed world and encouraging inroads have been made for millions in resource-limited settings. AIDS mortality and morbidity from opportunistic conditions have been dramatically diminished for those with access to care.

The initial use of AZT monotherapy in patients with late-stage HIV disease had a dramatic effect on mortality over the first several months of follow-up.¹⁰⁰ The benefits dissipated with the emergence of drug-resistant virus.^{99,134,200} The availability of additional nucleoside analog RT inhibitors, as replacement therapy on those failing AZT monotherapy and in combination with AZT in previously untreated patients, provided incremental efficacy.^{64,65,136,184} The use of nucleoside analogs in various combinations and regimens reduced morbidity and prolonged life. However, for most patients, drug resistance and loss of control ultimately ensued.

The approval of the first drugs in additional classes (NNRTIs and protease inhibitors) permitted the trials of two nucleosides and initially either indinavir or nevirapine, which changed the treatment paradigm.^{128,137,257,342} When patients

FIGURE 13.15. Time-line of acquired immunodeficiency syndrome (AIDS) therapies. The dates of important events in the understanding and therapy of AIDS are provided together with the dates of U.S. Food and Drug Administration (FDA) approval of antiretroviral drugs. The bars represent the progressive accrual of approved drugs. Abbreviations: ZDV, zidovudine (AZT); ddI, didanosine; ddC, zalcitabine; d4T, stavudine; 3TC, lamivudine; SQV, saquinavir; RTV, ritonavir; IDV, indinavir; NVP, nevirapine; NFV, nelfinavir; DLV, delavirdine; EFV, efavirenz; ABC, abacavir; APV, amprenavir; LPV/r, lopinavir/ritonavir; TDF, tenofovir; FPV, fosamprenavir; ATV, atazanavir; ENF, enfuvirtide; FTC, emtricitabine; TPV, tipranavir; DRV, darunavir; RAL, raltegravir; MVC, maraviroc; ETV, etravirine; RIL, rilpivirine. Elvitegravir was approved in 2012.

who had not yet acquired too many compromising drug-resistance mutations received these triple combinations, they experienced suppression below assay detection for plasma HIV RNA. Many patients are now well into their second decade of HIV RNA suppression and immune restoration. AIDS-related morbidity and mortality are seen primarily in those without access to care. In those who are receiving effective antiretrovirals, the primary complications are related to chronic hepatitis, malignancies, or the accidents and illnesses facing the general population.

The chronic use of antiretrovirals revealed toxicities often not appreciated in the initial preclinical toxicologic assessment of the drugs or clinical trials. Side effects due to nucleoside analogs include bone marrow toxicity (AZT), pancreatitis (ddI), myopathy (AZT), fat wasting in face and limbs (d4T, AZT), lactic acidosis (AZT, d4T, ddI, zalcitabine [ddC]) and peripheral neuropathy (ddC, ddI, d4T, ddC^{28,69}). Most pro-

tease inhibitors were observed to induce hyperlipidemia and insulin resistance.²⁶⁸ The availability of more drug alternatives has led to the gradual selection of regimens that minimize toxicity, maximize potency, and improve convenience in terms of pill burden and dosing frequency to facilitate adherence.^{359,362} As the regimens become more convenient, more efficacious, and less toxic, the proportions of patients whose circulating HIV becomes fully suppressed is approaching 90% and the mortality curves continue to improve each year.^{119,224}

These increasing rates of successful initial treatment diminish the proportion of patients who newly acquire drug resistance. Moreover, the proportion of patients with long-standing resistance to nucleoside analogs acquired before the availability of effective combination therapy is diminishing. The numbers of patients with transmitted drug resistance, after initially rising, now appears to be stable or even diminishing, with improved suppression of ongoing replication in increasing

proportions of the population.¹¹⁹ The availability of multiple alternative drugs is important to address the needs of patients requiring treatment of drug-resistant virus. The phenomenon of cross-resistance within drug classes still leaves many patients with few or no options; however, with newer drugs this number is diminished in developed countries. Therapy for HIV thus requires continuing efforts in drug resistance testing and drug development to contend with a virus so proficient at latency, evolution, and escape.

With the appreciation that treatment is more likely to be effective and less toxic when initiated early, and there is risk with delaying therapy at almost any stage of HIV infection, treatment guidelines have shifted to recommending almost universal treatment if feasible.³⁶² It has been proposed that this practice can also reduce HIV transmission.¹¹⁹

Herpesviruses Therapy

HSV and VZV Therapies

The first effective application of antiviral therapy for a herpesvirus infection was the local application of the nucleoside analog, 5'-iodo-2'-deoxyuridine, for the topical treatment of HSV keratitis.¹⁸⁶ This application has the advantage of permitting high local concentrations of antiviral at the site of infection without the risk of systemic toxicity. Other anti-HSV drugs are now used for this application. The first effective antiviral for systemic use against HSV was vidarabine, a nucleoside analog converted by cellular enzymes to an inhibitor of HSV DNA polymerase. This intravenously administered drug improved biopsy-proven HSV encephalitis in a double-blind, placebo-controlled trial in 1977³⁸² and subsequently was shown to be effective against neonatal herpes and VZV infection in immunocompromised patients.^{379,381}

ACV, the mechanism of which is detailed in this chapter, heralded the second generation of antivirals for herpesviruses and set the standard for the development of antiviral drugs. It became the standard care after randomized, controlled trials of intravenous drug for serious systemic infections such as herpes encephalitis, neonatal herpes, and varicella zoster in immunocompromised hosts.^{13,377, 378–379} In addition, it was shown to be effective for the prophylaxis of HSV and VZV in transplant patients.^{321,322} As an orally available agent with negligible toxicity, it has become widely used for the treatment of primary and recurrent HSV-1 and HSV-2, the prophylaxis of recurrent HSV, and the treatment of uncomplicated VZV.^{85,90,168,247,254,265,302,347,371} The earlier in the presentation of symptoms, the more effective the treatment, and prophylaxis is more dependable than treatment. The appearance of resistant isolates has been remarkably rare in immunocompetent patients and occurs in a minority of immunocompromised patients. ACV-resistant HSV and VZV did become a significant challenge in patients with AIDS preceding the availability of combination antiretroviral therapy.³¹⁷ The expanded number of resistant infections reflected the number of patients with AIDS, the prevalence of recurrent HSV and VZV infection in these patients, and the duration and magnitude of these opportunistic infections, because of the severely reduced antiviral immunity in these hosts. In many, but not all of these patients, cidofovir or foscarnet showed activity against resistant infections,³¹⁸ but resistance to these DNA polymerase inhibitors has developed as well.^{118,319}

Two limitations of oral ACV have been its limited oral bioavailability (~15%) and short half-life. These limitations

require administration of large pills as often as every 4 hours. As described earlier in this chapter, valacyclovir and famciclovir overcome these limitations, and would have completely displaced the use of ACV except for the expiration of the ACV patent resulting in the availability of low-cost generic drug. Both valacyclovir and famciclovir can be used for applications of oral ACV. In addition, because of the more prolonged maintenance of higher levels of antiviral activity, they are also used for the treatment of serious but not immediately life-threatening infections previously treated with intravenous ACV, for example, herpes zoster in the immunocompromised host.^{20,367}

HCMV Therapies

As reviewed earlier in the chapter, the lack of potency of ACV against HCMV led to the development of ganciclovir. Ganciclovir is more toxic than ACV. However, it is the first-line therapy for HCMV disease in the immunocompromised host.

The most common opportunistic complication of HCMV in AIDS is retinitis.¹⁷⁸ Ganciclovir clears viremia and arrests the progression of destructive retinitis.^{32,178,360} HCMV disease develops in patients with AIDS who have fewer than 100 CD4 cells per ml; however, before reconstitution of the immune system with combination antiretroviral therapy, these patients uniformly reactivated disease with withdrawal of treatment, thus requiring chronic suppressive maintenance treatment with the consequences of drug toxicity and emergence of resistant virus.³⁸⁰ Ganciclovir is similarly effective for the treatment of colitis, esophagitis, polyradiculitis, and ventriculitis in patients with AIDS,⁸⁰ and HCMV pneumonia in renal transplant patients.¹⁵⁴

With the difficulties of daily intravenous ganciclovir for maintenance therapy, oral ganciclovir was studied despite its low bioavailability, which resulted in limited efficacy and selection for drug resistance. Some significant benefit for the management of retinitis was the local administration in the eye of ganciclovir (and some other anti-HCMV drugs) by injection or implant.²³⁴ This approach protects the eye with high local concentrations, but fails to address HCMV disease in the rest of the body.³⁸⁰ The eventual development of valganciclovir has now provided an orally bioavailable drug for HCMV that can achieve levels approaching those of intravenous ganciclovir without the cost, inconvenience, and complications. Although a significant advance, the introduction of effective combination antiretroviral therapy was more crucial, as it dramatically diminished the prevalence of HCMV disease and essentially eliminated the need of maintenance therapy for retinitis.

Foscarnet, cidofovir, and fomivirsen are also approved for the treatment of HCMV. Although equally effective for the treatment of HCMV retinitis, foscarnet is used only for ganciclovir-resistant HCMV infections because of inconvenience and toxicity.³⁶⁰ Cidofovir is also used for the treatment of ganciclovir-resistant HCMV, with the advantage of requiring administration only every 1 or 2 weeks due to its very prolonged intracellular half-life, but the disadvantage of renal toxicity.

Antiviral therapy has not yet been shown to significantly impact disease attributable to the other human herpesviruses, EBV, and HHV6, HHV7, and HHV8. Various explanations include the limited activity against these viruses of available drugs, the undesirability of testing a difficult drug like foscarnet that might nevertheless have activity, the difficulty of conducting clinical trials for some of these infections, and the

relatively small size of the perceived market. Aside from therapies against these other herpesviruses, there remains considerable need for new anti-herpesvirus drugs to combat infections resistant to the current drugs, and to overcome the pharmacological and toxicity limitations of the current anti-HCMV drugs. No available anti-herpesvirus drug effectively addresses the problem of viral latency.

Therapy of Viral Hepatitis

HBV Therapy

The complex natural history of HBV infection is described elsewhere in this text. Criteria based on disease stage and level of HBV viremia, and the availability of more effective drugs, have increased the treatment indications and the long-term success of therapy.^{94,391} An important complication is that chronic HBV infection implies that immune responses toward the virus are impaired. In addition, chronic HBV entails the existence of large numbers of cells containing covalently closed circular HBV DNA, a situation akin to herpesvirus latency. For all practical purposes, this may preclude eradication of HBV infection. Therefore, for therapy to be successful, the immune response must be restored, chronic antiviral suppression must be maintained, or both.

A significant proportion, but not all, carriers of HBV progress to cirrhosis, hepatic failure, or hepatocellular carcinoma. Antiviral therapy has been shown to prevent the development of these complications and, in fact, to reverse cirrhotic histopathology.³⁵³ Whom, when, and how to treat are decisions based on risk of progression and therapeutic index of the various treatments.^{94,391} Treatment efficacy is impacted by the regimen used as well as viral genotype, host genetics including ethnic background, disease and virologic status, age, and comorbidities such as HIV co-infection.

The therapy for HBV infections has evolved.^{94,391} The first effective antiviral therapy for HBV infection was recombinant IFN- α , initially injected three times weekly. Daily injections proved more effective. Pegylation of IFN- α to permit effective levels when injected once weekly improved both acceptance and efficacy. Interferon therapy does not suppress plasma HBV DNA in as high a proportion of patients as does therapy with nucleoside analogs when administered for 12 to 24 weeks. Following the cessation of treatment, however, patients receiving nucleoside analogue therapy only rarely sustain responses, whereas a small subset of patients treated with interferon maintain durable responses. Interferon therapy, in contrast to nucleoside analogs, has not been shown to select for resistant mutants. The use of interferon therapy is limited, however, by its cost, inconvenience, and substantial side-effect profile (fatigue, depression, leukopenia).

Five nucleoside analogs have been approved for the treatment of hepatitis B. The experiences with these drugs recapitulate many of the experiences of HIV therapy. 3TC, telbivudine, and adefovir reduce plasma HBV DNA levels an average of 4 logs over a period of 12 weeks, associated with improvements of liver inflammation and progression of disease. Unfortunately, continuing use was associated with increasing proportions of patients with resistant mutants who experience treatment failure.²²³ Entecavir and tenofovir have displaced other drugs for HBV infection because of their high rates of virus suppression with monotherapy and the low rates of emergence of drug-resistant virus during treatment.^{94,337,391} The combination of

tenofovir and emtricitabine, which is active against HBV, has been approved for the treatment of HIV and is used routinely in patients who are co-infected with HIV and HBV.

HCV Therapy

The same issues regarding who and when to treat that apply to HBV apply to HCV. Factors include impact on response of viral genotype, age, sex, disease stage, host genotype, and co-factors like concurrent HIV infection, renal disease, or alcohol use.¹¹⁶ One critical difference is that HCV has no DNA intermediate that precludes eradication. HCV is thus curable.

IFN- α administered three times weekly was the first treatment shown to be effective against HCV; however, only 15% to 20% of patients achieved a sustained response with 48 weeks of therapy.^{293,401} An analysis of viral dynamics concluded that the three-times weekly regimen of IFN- α provided waning activity between doses and that progressively increasing doses provided progressively increasing efficacy,²⁶⁴ leading to incrementally better rates of sustained virological response with daily dosing.^{153,401}

The introduction of pegylated IFN- α , permitting weekly dosing, and provided yet another increment in these rates. The addition of ribavirin added yet another increment to the rates of sustained virology responses,^{105,196,231,240,301} Approximately one-half of patients achieved sustained virological responses with this latter regimen; however, genotypes 2 and 3 respond appreciably better, whereas genotype 1 and patients with HIV co-infection respond less well.^{51,131,364} Other factors including disease stage, viral load, race, age, sex, and weight impact this regimen, as they do all preceding regimens.³⁴⁴ The remarkable impact of the IL-28b genotype on host responsiveness to IFN efficacy provides a substantial explanation for much of the individual variation in treatment responses.¹¹⁶ It is noteworthy that the treatment of HCV, as with HBV, can reverse liver fibrosis and reduce rates of hepatocellular carcinoma.^{175,294}

The resources and commitment to discovery and development of small molecules targeting HCV, called direct acting antivirals (DAAs), has surpassed that directed against HIV. Potent inhibitors of protease, RNA polymerase (both nucleoside analogs and nonnucleosides), NS5A, and other targets have been identified, and entered clinical trials.^{279,290,325} The dynamics of response to treatment are faster with HCV than HIV with as much as 3 to 5 log₁₀ reductions with many drugs in a matter of days. Similarly, with the high levels of HCV replication, drug-resistant mutants emerge with monotherapy in a matter of days. The initial clinical studies thus required examination of the incremental benefit of adding a candidate drug to the standard regimen of pegylated IFN plus ribavirin. The first HCV DAAs to be approved in 2011 were the NS3 protease inhibitors, telaprevir and boceprevir.^{10,179,291,333,400} These drugs have similar efficacies, and increase the sustained virological response (basically a cure) by approximately 25% to 30% over the proportion with such a response with IFN and ribavirin alone. These improved responses are encouraging; however, a substantial proportion of treated subjects fail (and often with protease-resistant virus). Moreover, the regimen still requires the relatively toxic combination of IFN and ribavirin.

The development of drugs with activities against a broad range of genotypes and targeting multiple targets, which include nucleoside NS3 polymerase inhibitors, nonnucleoside NS3 polymerase inhibitors of targeting multiple different sites,

NS5A inhibitors and nonimmunosuppressive cyclophilin-binding compounds among others provide promise for potent combination regimens that could cure HCV infection in 8 to 24 weeks without the need for IFN or ribavirin. The field of HCV antivirals has accelerated remarkably and developments were occurring at an encouraging pace by 2012, such that the state of the field will certainly be transformed. Should this promise be achieved, earlier and more comprehensive treatment would be indicated. One could even imagine efforts to systematically find asymptomatic carriers of HCV and treat them. This might dramatically reduce transmission, chronic hepatic disease, and liver transplantation, approximately one-half of which is attributable to HCV.³⁰

Influenza Therapy

Both the adamantane derivatives and the neuraminidase inhibitors have utility for both prophylaxis and treatment of influenza. The adamantanes, amantadine and rimantadine, reduce rates of illness by 70% to 90% when used prophylactically for influenza A.^{6,71,81,212} They have some quantitative activity in reducing viral shedding and diminishing the duration and severity of symptoms when used early after the onset of illness.^{133,368,397} These treatment effects are limited. Moreover no data have been generated on the treatment of severe disease requiring hospitalization.

Rimantadine has fewer CNS side effects than amantadine, especially in the elderly. In addition, rimantadine is not renally excreted, and thus requires no dosing adjustments in renal impairment. Neither drug is active against influenza B. Moreover, resistance has developed into a major problem. Resistant virus is often shed after several days of treatment and when illness is resolving.¹⁴⁹ This virus can be transmitted, thus eliminating prospects for prophylaxis of contacts of the treated patient. Because of the limited therapeutic efficacy of the adamantanes and their ready selection for resistance, recommendations for the use of the adamantanes have been primarily as prophylaxis for influenza A. Several subtypes of influenza A have become predominantly amantadine resistant, having first been seen in China where amantadine is included in over-the-counter cold remedies,²⁷ and allegations of its use on chicken farms have been made.²⁷⁸ Recent isolates of avian influenza (H5N1) have also been amantadine resistant.¹⁶

The neuraminidase inhibitors, zanamivir and oseltamivir, are effective for prophylaxis^{147,150,258} and treatment.^{145,148,365} of both influenza A and B. Zanamivir requires inhalational administration, risks of uneven distribution in the respiratory tract, and occasionally bronchospasm. Moreover, should systemic activity be needed, especially with H5N1 disease,⁷⁶ oseltamivir is the only option, although parenteral preparations of zanamivir and newer neuraminidase inhibitors are in development.¹⁶ Although the efficacy of neuraminidase inhibitors has not been documented for the treatment of complicated influenza requiring hospitalization, it is recommended as the agent for treatment and prophylaxis of influenza A and B, especially with the expanding prevalence of adamantane resistance. It was stockpiled for a possible epidemic of H5N1 infection for which oseltamivir has been shown to be effective in animal models,¹⁶ and for the pandemic H1N1 epidemic of 2009.

High-level resistance due to His to Tyr mutation in codon 275 of the N1 neuraminidase can emerge during treatment of H1N1 in children and in several patients treated for H5N1 infection.³⁷² This mutation does not confer cross-resistance to

zanamivir.^{127,375} By itself, the H275Y (H274Y in N2) mutation reduces fitness *in vitro* and *in vivo*,¹⁷⁷ although it is transmissible to ferrets.¹⁵⁶ However, as reviewed earlier in the section on neuraminidase inhibitor mechanisms, oseltamivir-resistant H1N1 viruses containing H275Y and secondary mutations that increase fitness have emerged, increasing the need for new therapeutic options and engendering intense interest in the epidemiology of resistance to anti-influenza drugs.¹⁴⁶

Conclusion and Future Directions

Antiviral drugs ameliorate viral disease and save lives. Understanding viral replication and virus–host interactions is crucial for understanding the mechanisms of antiviral agents and for the discovery of new ones. Likewise, antiviral agents provide the virologist with excellent tools with which to investigate viral biology and biochemistry, and the biology and biochemistry of virus hosts. Of the antivirals available today, most inhibit viruses at the genome replication stage. This stage will doubtless continue to be the target for new drugs that become approved for use in patients. However, more and more drugs that target other stages are entering clinical use (e-Table 13.1). There is still a great deal of unmet medical need that can be served by antiviral drugs, and we are still learning how to use them.

Summary

Acknowledgments

Both innate and adaptive immune responses mediate host resistance to virus infection. Elements of the innate immune system, especially type I interferons (IFNs), strongly influence the clinical outcome of a virus infection. Many viruses have evolved mechanisms to inhibit or evade innate immune responses, indicating the importance of those defenses in limiting virus infection. Innate immune responses also mediate important effects during the induction phase of an immune response and may influence the magnitude and composition of adaptive immune responses. Although memory or “training” of natural killer (NK) cells may occur in response to some antigens (Ags), NK cells do not have mechanisms for somatic diversification of their recognition receptors and are limited to germline sequence.^{315,343} The capacity for somatic diversification of B-cell receptors (BCRs) and T-cell receptors (TCRs), selection, and long-term memory are central properties of adaptive immunity. Therefore, vaccine-induced immunity that is established in advance of virus infection relies primarily on adaptive immune responses for protective efficacy. Vaccination depends critically on the properties of Ag recognition, activation, expansion, memory, trafficking, and effector functions inherent to lymphocytes. Subtle influences of vaccination on the timing, magnitude, specificity, quality, and location of responding lymphocytes and their effector molecules determine whether exposure to a viral pathogen results in infection, protection, subclinical infection, mild disease, or exaggerated disease expression. The extent to which vaccine-induced immunity is successful in an individual can determine the spread of virus within a population (e-Fig. 14.1). Thus, vaccines have a profound effect on public health through the control of epidemics (e-Fig. 14.2). An antigenic stimulus that elicits a virus-specific adaptive immune response that can be recalled during subsequent virus infection defines it as an immunization. A vaccination is an antigenic stimulus delivered by intention.

VIRAL ANTIGENS RECOGNIZED BY THE IMMUNE SYSTEM

Development of an immune response to Ags present on the surface of virions or virus-infected cells is often critical for immunity against virus infection. Antibody (Ab) responses to surface viral protein or glycoprotein Ags often effectively limit infection of new cells and thus spread of the virus. Internal viral Ags can be important targets for T-lymphocyte responses that clear virus-infected cells; however, these responses alone cannot prevent subsequent infections (e-Fig. 14.3). The relative

importance of Abs to surface proteins and of T-cell responses to internal proteins in influenza virus was illustrated by studies of the 1957 Asian influenza pandemic and the 1977 “Russian” influenza epidemic. The 1957 Asian influenza A (H2N2) virus contained surface glycoproteins (the hemagglutinin [HA] and the neuraminidase [NA]) that were novel, such that the human population had not been exposed to strains containing these or related surface Ags. In contrast, the major internal proteins of the new H2N2 virus, the nucleoprotein and the matrix protein, were closely related to corresponding Ags of previous strains of subtype H1N1 to which most individuals had been exposed. Although recent infection with heterotypic viruses may have diminished the level of illness severity in adults,¹²⁶ the population’s prior immunological experience with related internal Ags did not prevent the 1957 Asian H2N2 influenza A virus from causing a major pandemic.³⁰³ In contrast to this experience, observations following the re-emergence of the H1N1 virus in 1977 indicated that homotypic humoral immunity provided a high level of resistance that lasted for decades. Similarly, humans exposed to the 1918 influenza H1N1 virus as infants sustained circulating memory B cells encoding neutralizing Abs to the HA into the 10th decade of life,⁴⁶⁷ and these Abs cross-reacted with the 2009 H1N1 pandemic strain and provided protection.^{233,462} Induction of cross-reactive Abs to influenza may sometimes be harmful. For example, immune complexes with complement deposition have been demonstrated in lung tissues of victims of pandemic influenza.²⁸⁷ Additional evidence for the importance of responses to influenza A surface glycoproteins was provided by passive and active immunization studies in mice. Monoclonal antibodies (mAbs) directed against the HA or NA proteins protected mice against challenge with virulent wild-type virus, whereas mAbs specific for the internal nucleoprotein or matrix protein did not alter the course of disease.³⁰³ Immunization with recombinant vaccinia viruses expressing each of the 10 known influenza A gene products showed that only recombinants expressing the HA or the NA glycoprotein induced resistance to virus challenge.¹²⁴ Whereas the vaccinia vector-induced CD8 T-cell-mediated immunity specific for internal viral proteins provided some measure of heterosubtypic cross-reactivity against influenza challenge,¹²⁵ the aggregate data suggest that a successful strategy of immunoprophylaxis against most virus infections requires the generation of an immune response to the surface Ags displayed on virions and on virus-infected cells. Other viruses (such as poxviruses, herpesviruses, filoviruses, some respiratory viruses, and lentiviruses) that have a more complex pathogenesis may require vaccines that induce more complex immune responses for protection from infection or control of disease. Many of these viruses possess the capacity for persistence, infect immunoprivileged sites, use sophisticated immune evasion strategies, directly infect their target organ without a requirement for viremia, or cause disease by eliciting an aberrant host response. Vaccine development for these viruses probably will require the induction of neutralizing Abs against surface proteins to protect against infection in addition to T-cell responses against structural and regulatory proteins to control virus spread and to modulate the composition of the immune response.¹⁶⁷

The surface glycoproteins of enveloped viruses and the capsid proteins of nonenveloped viruses are the primary target Ags for Ab-mediated protection. The following generalizations can be made about the nature of Abs and their interaction with

virus surface proteins. First, antiviral Abs against the extracellular domain of surface proteins predominantly recognize conformational epitopes. Such conformational epitopes are difficult to mimic with peptides or proteins that have had the structure of antigenic sites modified by vaccine preparation and formulation. Presentation of the native Ag structure in its authentic conformation is critical for induction of neutralizing Abs. Even when the structure is mimicked with atomic-level precision and elicits Abs that bind the epitope, the property of viral neutralization may not be achieved.^{274,326}

Most viral surface proteins assemble into oligomeric states on virions, typically dimers, trimers, or tetramers; however, the monomeric form of the protein is also present in cell debris or shed proteins. The principal neutralizing determinant may be present only in quaternary structures; thus, Abs binding to monomeric protein do not recognize or neutralize virions. In addition, many surface proteins that are targets of neutralizing Abs are fusion proteins present in a metastable state on virions. During the attachment and fusion process, the fusion proteins transition from prefusion to postfusion forms, in some cases drastically altering the structure of neutralizing epitopes. Second, Abs recognize many major antigenic sites on each viral protein, and within each of these antigenic sites, there may be multiple epitopes. For example, the parainfluenza virus attachment glycoprotein (HN) has at least six antigenic sites, three of which are recognized by neutralizing Abs.⁸⁵ After infection, individuals often develop Abs only to a subset of the antigenic sites of the infecting virus.⁸⁶ After one or more reinfections, the Ab response broadens to recognize more antigenic sites. These findings provide a partial explanation for the failure of immunization to induce complete immunity in certain circumstances and also provide a rationale for recommending multiple immunizations to achieve optimal protection. Third, the large size of immunoglobulin (Ig) molecules often precludes direct access to functional sites on viral surface proteins, such as the receptor binding site, sites with enzymatic activity, or fusion peptides. Such domains can be buried within the protein structure of the surface protein or masked by carbohydrate molecules, variable loops, or conformational flexibility.²³⁶ As a consequence, the critical sites vulnerable to Ab-mediated neutralization can remain relatively inaccessible. Therefore, Abs usually exert their antiviral activities by mechanisms other than direct inactivation of functional sites on the surface proteins. Instead, Abs most often act directly or indirectly to impede attachment of virus to the cell or to prevent uncoating of virus that has attached to or entered the cell. Unfortunately, effective Ab-mediated protection against virus infection is not always achievable. For example, the Ab response to the envelope glycoprotein of human immunodeficiency virus (HIV) evolves over time similar to the response elicited by repeated infections with parainfluenza virus; however, the elaboration of the envelope-specific Ab repertoire is not able to keep pace with the rapid genetic evolution of the virus. The Abs present at a given point in time may neutralize virus isolated from the subject 6 months earlier, although they have very low neutralization activity against current strains that have mutated extensively.³⁶⁸ Sufficiently high levels of passively administered broadly neutralizing mAbs can prevent simian-human immunodeficiency virus (SHIV) infection of macaques in some settings.²⁶⁵ SHIV is a chimeric lentivirus with the internal and regulatory proteins of simian immunodeficiency virus (SIV) and the surface

glycoprotein (gp160) of HIV-1. However, immunization with currently available HIV-1 envelope Ags does not elicit Abs with these neutralizing properties. There are also examples from Ebola virus,⁴⁴⁵ vaccinia virus,^{31,271} and lentivirus³⁹³ models that demonstrate settings in which both Ab and T-cell responses contribute to vaccine-induced protection. Ags for eliciting T-cell responses can be surface proteins, internal structural proteins, or regulatory proteins. For example, the major CD8 T-cell responses to HIV-1 are directed toward Gag, Pol, and Nef proteins.³⁶ Often, the nucleocapsid and matrix proteins of viruses are found to encode important cytotoxic T lymphocyte (CTL) epitopes,⁴²⁸ perhaps because they are typically more abundant, more conserved, and produced earlier in the virus life cycle than surface proteins.

VACCINE-INDUCED IMMUNITY

Immune mechanisms have evolved to protect the host against a diverse assortment of viral pathogens. Viruses and their hosts co-evolve; viruses find ways to evade host defenses, and hosts adapt mechanisms to control virus replication. The host is equipped with mechanical barriers and innate immune mechanisms that can limit the initial encounter with a virus and adaptive immune mechanisms that provide immunity against repeated exposures to the same viral pathogen. Although innate responses are important during the induction phase of vaccine-induced immunity, humoral and cellular adaptive responses are the primary effector mechanisms of protection from future infection (e-Fig. 14.4). Humoral and cellular responses are complementary in that Ab is able to prevent infection by free virus; however, when infection occurs despite innate defenses and the presence of neutralizing Abs, T-cell responses are designed to eliminate virus-infected cells and diminish the subsequent release of infectious virus. The repertoires of BCRs and TCRs have also evolved complementary strategies to deal with genetic variation in viruses. For a given antigenic site on a viral protein, most hosts can expand a B-cell population that can recognize the structure. This leads to population-wide protection against reinfection with a particular virus. In turn, this forces antigenic change in the virus, often resulting in a new serotype, which is not recognized by the original Ab. Therefore, the host has to start over in the generation of Ab-mediated type-specific protection. In contrast, T-cell epitopes are not shared between hosts unless they happen to share the same major histocompatibility complex (MHC)-restricting allele. Consequently, each infected host generates T-cell responses against a limited number of viral epitopes that are largely determined by human leukocyte antigen (HLA) haplotype. Unlike Ab epitopes, T-cell epitopes are often cross-reactive between viral serotypes and thereby provide the Ag-experienced host with partial protection against new virus strains until the Ab responses can adapt (e-Fig. 14.5).

When virus breaches the physical and innate barriers and infects a target cell, several rounds of replication may occur in a primary infection before the adaptive immune responses are established (e-Fig. 14.6A). Depending on the virus, this may result in spread to the target organ of disease and/or establishment of a persistent infection. The timing, magnitude, location, and qualitative features of the host response will determine the clinical outcome of infection. In persistent virus infections

(e.g., HIV, hepatitis C virus [HCV], or herpes simplex virus [HSV]), the disease manifestations are often congruent with virus replication. In self-limited infections (e.g., influenza, respiratory syncytial virus [RSV], or dengue), the bulk of disease is often after the peak of viral replication, although in some cases disease can also be temporally associated with viral load (e-Fig. 14.6B). In cases of persistent or latent virus infection, the immune response attempts to limit virus replication or spread. Control of the magnitude and composition of complex immune responses is critical to avoid immunopathology. Fortunately, there is considerable redundancy inherent in immunity to viruses. For example, while CD8 T cells are the primary mediator of cytolytic activity, this function also can be accomplished by complement or by NK cells targeting the Fc portion of Ab labeling virus-infected cells. Another well-studied example of this redundancy involves CD4 and CD8 T cells, either of which are sufficient to achieve clearance of virus, as shown in studies of influenza A virus or poxviruses in mice. Animals lacking CD8 T cells readily clear influenza virus or vaccinia virus from the lungs, indicating that CD4 T cells and Ab are sometimes sufficient for viral clearance.^{271,390} The therapeutic efficacy of Abs acting in the absence of other immune functions has also been demonstrated in experimental influenza A virus infection of mice. Abs to the influenza A virus surface HA have cleared virus from the lungs of persistently infected severe combined immunodeficiency (SCID) mice.³⁹⁰ Whereas CD8 T cells are specialized in recognition and clearance of virus-infected cells, CD4 T cells (plus the Abs secreted by B cells for which they provide help) and CD8 T cells can mediate viral clearance independently. The relative importance of these two arms of the immune response varies in the resolution of particular virus infection. Even in the case of lymphocytic choriomeningitis virus (LCMV), the prototypic arenavirus, which in the murine model is a paradigm for CD8 T-cell-mediated immunity, Abs and CD4 T cells each make a significant contribution to the resolution of primary virus infection.²¹ In general, Abs are the major mediator of resistance to reinfection with virus, and CD8 T cells are the major mediator of clearing virus-infected cells. CD4 T cells are critical for the induction of robust Ab responses and important for “helping” CD8 T-cell responses; they also have potential for direct antiviral effector functions. Abs work best when the target organ for disease pathogenesis is distinct from the initial site of infection, particularly in cases where the virus has to travel through the bloodstream to reach its target organ. For example, in diseases such as measles, polio, hepatitis, or the viral encephalitides, where viremia must be established to cause disease, it often takes very small concentrations of pre-existing Abs to achieve clinical protection. Because it is rarely possible to elicit sufficient Ab through vaccination to prevent virus infection completely, other immune mechanisms must contribute to vaccine-induced immunity.

One reason why live virus vaccines are so effective is that many components of both innate and adaptive immunity are engaged. The protein, nucleic acid, carbohydrate, and lipid components of viruses induce innate responses through a variety of toll-like receptor (TLR) and other pathogen-associated molecular pattern (PAMP) receptor interactions. Virus infection induces all components of the adaptive immune response—Ab responses are induced against viral surface proteins in their native conformation, CD4 T cells are stimulated,

and importantly, viral proteins are produced in the cytoplasm, processed, and presented in MHC class I molecules for induction of CD8 CTL responses. All of these responses are needed to achieve the optimal clinical outcome from a virus infection. Abs and innate defenses provide the initial barrier to infection by neutralizing incoming virus. After the virus has infected a cell, however, it is then incumbent on the innate defenses to control the virus until the adaptive cellular immune response can be activated, expand, and traffic to the affected tissues. In the immune host, the pre-existing Ab will prevent or limit the number of infected cells, and rapid mobilization of memory T-cell responses will rapidly clear virus-infected cells (e-Fig. 14.7A). Although cytolytic T cells are potent in their ability to clear virus-infected cells and reduce the spread of virus, it comes at a cost. The T-cell response can injure the host as it clears the virus and is thus tightly regulated. Turning the immune response off is just as important as turning it on for the well-being of the host. The system is biased toward controlling inflammation, and that may be a reason why the T-cell response is regulated to require several days to activate and expand. Influencing the events in this period between virus exposure and the fully activated primary T-cell response is one of the key factors in determining the efficacy of vaccine-induced immunity, for which the goal is to prevent, abort, or control virus infection to avoid clinical disease (e-Fig. 14.7B).

Vaccine-Induced Cellular Immunity

MHC class I-restricted CD8 cytotoxic CTLs and MHC class II-restricted CD4 helper T cells (Th cells) each function independently as Ag-specific antiviral effector cells (Chapter 9). Intact cellular immunity is critical for protection against some types of viruses. For example, most herpesvirus infections become more severe and destructive when cellular immunity is compromised. Vaccinia can cause progressive tissue invasion in persons with cell-mediated immune deficiencies. RSV and parainfluenza type 3 often become lethal infections in the setting of SCID or in patients who have undergone bone marrow transplantation. In contrast, patients with Ab deficiencies experience more severe disease only from selected viruses, particularly picornaviruses.

CD8 T Lymphocytes

CD8 T cells are the major T-cell effectors of antiviral activity. They are often referred to as CTLs, although they can clear virus-infected cells by both lytic and noncytolytic mechanisms. The CD8 TCR recognizes a short peptide derived from an endogenously produced viral protein in the context of the MHC class I β 2-microglobulin heterodimer expressed on the surface of an infected cell. Ag presentation by the MHC class I β 2-microglobulin heterodimer is restricted to viral peptides that are produced and processed during infection. Therefore, the major CTL functions are to eliminate infected cells¹³⁴ or to inhibit virus replication by the elaboration of soluble mediators such as cytokines^{138,299,425} or chemokines.^{77,464} The net effect of CTL activity is to prevent further spread of virus and to terminate infection in cells that are already infected. The importance of CTLs in recovery from virus infection is indicated not only by the association of cellular immune deficiencies with severe virus infection but also by the diverse strategies that viruses use to escape from CTL immunity.⁴⁰⁸ Viruses such as herpesviruses, poxviruses, and lentiviruses in particular have evolved

strategies for interfering with Ag presentation pathways or CD8 T-cell effector molecules that compromise CTL activity. Lentiviruses are prototypes for escaping CTL killing by genetic variation and selecting mutations of key epitopes. CD8 T-cell activity is critical for controlling SIV replication.³⁹³ When that control is mediated by a dominant CTL response to a single epitope, immune control of viremia is lost when that epitope is altered by mutation.²⁴

Although CTL antiviral activity generally is associated with the clearance of virus and the reduction of virus-associated pathology, disease enhancement can be observed under experimental conditions in which CTLs have been transferred passively to virus-infected recipients.^{58,121,293} Therefore, one can view the immunopathology caused by the T-cell response to virus infection as the cost for virus clearance. A major goal of vaccination is to induce CD8 T cells with properties to clear virus-infected cells efficiently and rapidly to minimize the immunopathology associated with virus infections.

The time course of CTL activation during virus infection in the lungs is consistent with its important role in clearance of primary virus infection. Primary CD8 CTL activity in lung peaks at about day 7 during acute virus infection, such as that produced by influenza A virus, LCMV, or RSV.^{14,134,209} The naive CD8 T cell in the LCMV model undergoes a process of activation and expansion during that time of 10,000- to 50,000-fold.⁴⁰ After about 40 days, the level of detectable virus-specific memory CD8 CTL is about 10% of that during acute infection and is then maintained at constant levels for years even in the absence of Ag.²⁰⁹ Each successive virus infection adds an expanded set of specificities to the pool of memory CD8 T cells over time and shapes the capacity of the host to respond to selected viruses.^{398,399} The memory CD8 T-cell pool not only has an increased precursor frequency against virus-specific epitopes; those cells also have a faster response time. The influence of CD8 CTL memory on the outcome of a subsequent virus exposure can be subtle and may depend on the absence or presence of other components of the immune response. For viruses in which a significant component of the clinical syndrome is related to the immune response clearing the virus, having memory CD8 T-cell responses will result in reduced virus replication a day or two earlier than in primary infection, an earlier peak illness time point, and a lower peak magnitude of illness.^{138,168} In a setting where there is a large viral load (e.g., high inoculum challenge) and an absence of pre-existing neutralizing Abs to diminish the number of virus-infected cells, a large CTL response or infusion of excessive CD8 T cells can result in more severe disease.⁵⁹

To date, T-cell response has not been used successfully as a correlate of immunity that is the basis for licensure of a vaccine. However, the incorporation of CTL epitopes into viral vaccines has been considered valuable because of the important role that CTLs play in clearance of established virus infections. The following characteristics of the CTL response *in vivo* should be kept in mind when designing a vaccine for viruses that may require a CTL component of immunity. First, the ability of a CTL epitope to induce an immune response is MHC dependent. Therefore, the incorporation of large antigenic content is important so that multiple CD8 T-cell specificities can be elicited by the vaccine to allow selection of epitopes by the diverse repertoire of human MHC class I alleles and to reduce the possibility of immune escape through genetic mutation. Second,

when considering vaccine-induced immune protection, CTLs represent a second line of defense against virus infection because they cannot prevent infection and are only effective against infected cells. The localization and phenotype of CD8 T cells can influence the timing and efficiency of viral clearance. For example, immunization of macaques with a recombinant CMV vector that induces a sufficiently high frequency of intraepithelial effector memory CD8 T cells can rapidly clear virus-infected cells following SIV challenge, leading to abortive infection.¹⁸⁵ Technologies such as polychromatic flow cytometry,³⁴⁸ MHC class I tetramer reagents that provide the means to sort epitope-specific T cells,¹⁰⁸ the ability to define functional subsets of T cells with more precision,¹⁰⁵ sequencing technology that allows single-cell clonotyping of epitope-specific cells, and correlation of the TCR-peptide-MHC biophysical interaction and structure with T-cell functions³⁷ may provide the necessary information to harness CD8 T cells more effectively in the future.

CD4 T Cells

CD4 T cells provide a variety of functions, including help to B cells and CD8 T cells, thereby augmenting the two major effector mechanisms of the adaptive immune response. CD4 T cells can also mediate direct antiviral activity *in vivo*^{188,262,296,426}; however, this is not their major function as it is for CD8 T cells. The MHC class II, $\alpha\beta$ heterodimer—the restricting element for CD4 T cells—is present predominantly on antigen-presenting cells (APCs) such as dendritic cells, macrophages, monocytes, and B cells. However, during inflammation, even epithelial cells can express MHC class II molecules, and CD4 T cells have been shown to have compensatory viral clearance capacity in the absence of CD8 T cells. In addition to having antiviral and helper activity, CD4 T cells can mediate immunopathology^{12,279,422} and have been shown to have regulatory and other specialized functions⁴⁷⁶ (e-Fig. 14.8).

The CD4 T-cell response to certain internal viral proteins may play a cooperative role in the development of effective resistance by augmenting the Ab response to a major surface protein.³⁸⁰ For example, immunization with the membrane (M) protein of influenza A virus can prime for a subsequent augmented Ab response to the HA glycoprotein on virus particles.³⁸⁰ In this manner, the entire CD4 T-cell repertoire developed against the viral surface and internal proteins can be called into play to amplify a B-cell response to a surface protein. Because MHC class II–restricted T-cell epitopes tend to be more numerous on viral proteins than MHC class I–restricted epitopes,²³⁴ the repertoire of CD4 T cells capable of augmenting the Ab response is large. Although CD4 T cells are typically thought to provide indirect helper functions to improve CD8 T-cell and Ab responses, there is evidence that they may also contribute direct effector functions to virus clearance. CD4 T cells have been shown to have cytolytic function against HIV.³²⁹ Viral Ags can induce a protective immune response mediated by CD4 T cells in the absence of B cells or CTLs,²⁶² indicating that this arm of the immune response can make an independent contribution to resistance against both acute and chronic virus infections.¹⁸⁸ CD4 T cells also secrete IFN- γ , tumor necrosis factor (TNF)- α , and other soluble factors that may directly inhibit virus replication.^{322,323} For these reasons, it is advisable to include virus Ags capable of inducing CD4 T-cell responses in viral vaccines to achieve maximal

immunogenicity. The processes involved in CD4 T-cell memory induction are distinct from the processes involved in establishing CD8 T-cell memory responses³⁹⁷ and more complex in some ways. Ag processing and presentation in MHC class II molecules can occur through the endocytic pathway; therefore, unlike CD8 T cells, CD4 T cells can be induced by killed virus vaccines or even purified proteins and do not require live virus or gene delivery approaches to allow Ag to reach the cytoplasm. CD4 T cells do not proliferate to the same extent as CD8 T cells during primary infection, and those producing IFN- γ do not survive as long-lived memory cells.⁴⁷²

CD4 T cells have traditionally been considered “helper” T cells (Th), and indeed their activities can improve the potency of B-cell and CD8 T-cell responses. In addition to the original subsets Th1 and Th2, there are now many subpopulations of T cells defined with distinct functions, some of which can alter or diminish effector function. For example, CD4+FoxP3+ T cells have been found to have inhibitory effects on other immune effector functions, hence the name T-regulatory cells, or Tregs.³⁰ The extent to which vaccines induce CD4+FoxP3+ T cells with T-regulatory activity is not well defined. In addition, there are other subsets of CD4 T cells that produce interleukin (IL)-17 and other proinflammatory cytokines that have been associated with immune-mediated pathology but are also important for immunity against some pathogens. More recently, a CD4+CXCR5+ subset of CD4 T cells designated T-follicular helper (Tfh) cells has been identified that resides primarily in lymph node germinal centers and promotes B-cell memory and plasma cell differentiation.⁹⁵ The role of each CD4 T-cell subset in vaccine-induced protection and optimal balance is an area that needs more investigation.

Vaccine-Induced Humoral Immunity

The correlates of immunity that have been established to date for licensed viral vaccines have been associated with Ab responses. In fact, the rationale for development of many of the vaccines in use today was the evidence derived from clinical trials of Ab treatments showing that Abs could mediate protection against disease. Passive transfer studies established the efficacy of Abs in preventing or treating virus infections and disease caused by a wide variety of viruses belonging to diverse RNA or DNA virus families that include the orthomyxoviruses, paramyxoviruses, alphaviruses, flaviviruses, arenaviruses, lentiviruses, picornaviruses, hepadnaviruses, and herpesviruses. Examples of the licensed clinical use of Abs include preparations for hepatitis A and B viruses, measles virus, poliovirus, VZV, rabies virus, RSV, and cytomegalovirus (CMV). A large number of new human mAbs have been discovered in the past decade, and some are under development as prophylactic agents.

A long history of Ab treatments laid the groundwork for current vaccine strategies. Commercial human gamma globulin, which usually contains 16% to 18% immunoglobulin G (IgG) is highly effective in preventing hepatitis A disease and was used widely for that purpose during the past 50 years, even though only a small proportion of the Abs in the preparations are specific for that virus.⁸⁹ Currently, inactivated or recombinant protein vaccines for hepatitis A are licensed and thought to work by inducing serum Abs to the virus. A historic double-blind, prospective clinical trial performed in 1951–1952 showed that human IgG also was effective in preventing

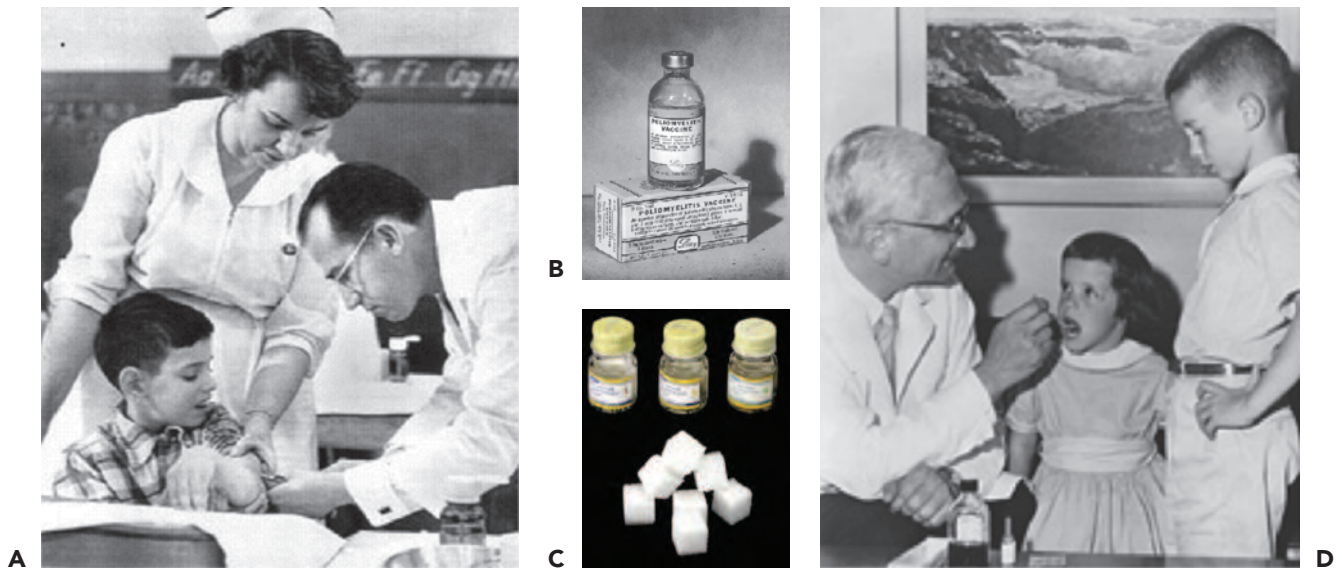

FIGURE 14.1. Polio vaccine development. The development of vaccines for polio brought the process of vaccine development into the public eye and was the first licensed vaccine that relied on mammalian cell culture. Jonas Salk (**A**) spearheaded the development of the inactivated polio vaccine (**B**). The development of the oral polio vaccine (**C**) was headed by Albert Sabin (**D**). These two vaccines are still in use today and over the past 50 years have nearly eliminated poliovirus, making the goal of global eradication feasible. (**A**, © AP Wide World Photos; **C** and **D** courtesy Hauck Center for the Albert B. Sabin Archives, Henry R. Winkler Center for the History of the Health Professions, University of Cincinnati.)

paralytic disease caused by poliovirus.¹⁸¹ Intramuscular inoculation of 0.3 mL of IgG/kg conferred significant resistance that lasted for at least 5 weeks. This seminal observation showed that Abs alone can confer resistance to poliomyelitis and suggested that vaccines inducing such Abs might protect against the disease. Subsequent field trials of inactivated vaccines by Salk and live attenuated vaccines by Sabin validated this view, leading to implementation of universal immunization against poliovirus and ultimately the current worldwide campaign for elimination of polio disease (Fig. 14.1). Before the live measles virus vaccine was licensed for routine use in immunization of young children, human IgG was used for passive prophylaxis and was the mainstay for prevention of disease. IgG given at a dose of 0.5 mL/kg prevented measles, even when administered to exposed individuals as late as 3 days after inoculation with virus.²⁰² Human IgG prepared from pooled plasma selected for a high titer of varicella-zoster virus (VZV) Abs (varicella-zoster immune globulin [VZIG]) is licensed in the United States for use in prevention of severe varicella in immunosuppressed children.⁴⁷¹ Most of the exposed immunosuppressed children receiving treatment still become infected; however, most exhibit attenuated disease or subclinical infection. Live attenuated varicella virus vaccine was licensed and recommended for universal immunization in 1995. Human IgG was effective in preventing chronic hepatitis B virus (HBV) infection in high-risk infants following maternal exposure.²⁸ Hepatitis B immune globulin and subunit vaccine are now used in concert to protect infants in this setting.

Preclinical studies in animals suggested that serum RSV-neutralizing Abs above a threshold titer were protective against lower respiratory tract infection, and this observation was validated during a clinical trial of human IgG containing a high

titer of RSV-neutralizing Abs that led to licensure in 1995.^{1,359} Of interest, the level of serum RSV-neutralizing Abs required for reduction of hospitalization was similar to that needed to prevent infection in cotton rats. A second-generation approach—the use of a humanized murine-neutralizing mAb to RSV—was licensed in 1998.² To date, this is the only mAb licensed for prevention of an infectious disease. These clinical applications strongly suggest that neutralizing Abs are an important correlate of protection for RSV vaccines, which are under development. Immunosuppressed patients who have not been infected previously with CMV, a herpesvirus, are at high risk of developing severe life-threatening disease following exposure to the virus, especially when they receive an organ transplant from a CMV-infected donor. Administration of CMV IgG, prepared from pooled units of plasma selected for a high Ab titer, prevents approximately half of the serious illnesses attributable to CMV but does not prevent infection.⁴⁰⁵ This finding is interesting because the mode of action suggests that Abs suppress disease by their action on CMV-infected cells and that Abs with these properties should be a target for CMV vaccines under development.

Mechanisms of Virus Neutralization

Abs may render free virus noninfectious, principally through neutralization of infectivity. Virus-neutralizing activity typically is measured by *in vitro* assays in which Ab and infectious virus are incubated and then inoculated onto cell culture. Residual infectivity is quantified by plaque count, infectious foci, signal from recombinant reporter virus, percent of infected cells detected by flow cytometry or other methods and compared to untreated suspensions. Viruses are neutralized *in vitro* by Abs by a wide variety of mechanisms. Important Ab

characteristics include affinity/avidity, isotype, concentration, Ab-to-virus ratio, valency, state of polymerization, ability to bind the polyimmunoglobulin receptor (pIgR), ability to fix complement, and specificity for the virus protein and epitope of interest. Virus-related factors important to neutralization include general aspects of the replication cycle of the virus under consideration (receptor use, mode of entry into the cell, pH dependence of fusion, site of replication) and individual characteristics of the specific virus strain (antigenic subgroup and amino acid sequence of viral surface proteins). Host factors influencing the mechanism of neutralization include the type and origin of cells and the level of expression of membrane receptors. The most potent mechanisms of neutralization act prior to infection of cells. First, free infectious virions in solution can be aggregated by multivalent Abs directed against surface glycoproteins.^{17,331} The consolidation of multiple infectious virions into an aggregate reduces the number of available infectious units. Second, Abs can inhibit virus attachment to cells, usually by binding directly to virus attachment proteins. Abs to attachment proteins often are poorly neutralizing *in vitro*, effecting only partial neutralization even at high concentration.²¹¹ This effect may be caused by virus heterogeneity owing to a variable extent of glycosylation that occurs during posttranslational processing at the numerous glycosylation sites on these proteins, or because of multiple routes of entry or mechanisms of attachment. Third, viruses can be neutralized following attachment, at the cell surface prior to cell entry, suggesting that immune serum contains Abs capable of inhibiting entry into the cell. For example, Abs to human papillomavirus (HPV) can interrupt infection at two stages of attachment and entry: the first an initial association with the acellular basement membrane that induces conformational changes in the virion and second the association of virus with the keratinocyte cell surface.¹⁰⁴ Some neutralizing Abs decrease infectivity by inhibition of virus–cell fusion at the plasma membrane. Fusion inhibition (FI) activity for some Abs has been inferred from *in vitro* assays in which Ab is incorporated into overlay medium after virus absorption and penetration, and activity measured by inhibition of postinfection cell-to-cell fusion. Additionally, Abs can inhibit the release of progeny viruses from infected cells. There is even evidence that some influenza virus–specific Abs inhibit virus replication by preventing the primary uncoating of virus that is associated with low-pH membrane fusion in the endosome or at the step of the secondary uncoating of the virion core structure—a step required for primary transcription of the virus genome.^{330,332} Our current understanding of the induction of such Ab functions is not sufficient to allow us to design specific vaccine strategies to induce them.

Structural and Biochemical Features of Antibodies Important to Affinity

Abs induced by primary infection or immunization are generally of low affinity for the target Ag. Affinity maturation of Abs is mediated by somatic mutation of the genes encoding B-cell receptors, which occurs in germinal centers, most prominently following second infections or booster doses of vaccine. Somatic hypermutation (SHM) coupled with B-cell selection results in the promulgation of high-affinity Abs in the antiviral repertoire. Increases in affinity likely increase neutralizing potency for most antiviral Abs directed to surface proteins. Although the molecular basis for affinity maturation during

secondary responses was not understood during the development of early vaccines, the enhanced efficacy of multiple-dose vaccine regimens in clinical trials pointed the way to a practical use of this principle. Most licensed viral vaccines are administered using multiple-dose regimens to enhance the quality, magnitude, and durability of the immune response.

Increased affinity is widely believed to confer enhanced functional competence on Abs. Work using HIV-1–specific Abs derived from combinatorial phage display Ab libraries demonstrated improvements in neutralization associated with affinity maturation caused by SHM.⁴²⁷ The fusion (F) protein—the major protective Ag of RSV—has at least four antigenic sites, each with a differing capacity as a target for virus neutralization.²⁹ Recombinant derivatives of a humanized RSV mAb containing random mutations in the combining site have shown that mutations enhancing the association rate improved neutralization and efficacy, whereas mutations improving the dissociation rate did not, despite their contribution to improved steady-state affinity.⁴⁵⁸ Somatic mutations in human rotavirus Abs have been shown to enhance affinity and inhibitory function, with individual mutations in Ab combining sites conferring several hundred-fold increases in affinity and function.²¹¹ The broadest and most potent human Abs to HIV and influenza virus isolated to date are distinguished by exceptional numbers of somatic mutations in the Ab sequences (on the order of about one-third of nucleotides altered).^{467,474} Hypermutation introduces not only point mutations that enhance function, but in some cases nontemplated insertions of sequences encoding new amino acids that mediate neutralization.²³³ In the vesicular stomatitis virus (VSV) mouse model, investigators have shown only modest increases in the affinities of hypermutated Abs compared with those in germline configuration over the course of infection and after repeated booster injections.²¹⁰ The VSV G glycoprotein is unusual in that it contains only a single immunodominant antigenic site that reliably induces neutralizing Abs. Neutralization activity also is determined by the number of times the neutralizing determinant is displayed on the surface of the virion, and some studies suggest that virion particles may be dynamic in their display of epitopes.¹¹² Understanding the relationship of affinity and neutralization is needed so that we can better appreciate the B-cell response to exposure with foreign Ags in a physiologic context. Furthermore, elucidation of the role of affinity in antiviral Ab function is critical for designing new active and passive immunization strategies against pathogenic human viruses. The absence of somatic mutations in the virus-specific Ab sequences of infants probably accounts for the difficulty in inducing high-affinity, high-potency Abs in this population after a single vaccination.⁴⁴⁸

CDR3 Loops of the Antibody Variable Region in Antigen Binding

A combining site formed by the variable heavy (V_H) and variable light (V_L) domains of the Ab fragment (Fab) mediates Ag recognition. Both the V_H and the V_L chains have three noncontiguous linear sequences of greatest variability—CDRs—that result in flexible loops in the Ig protein and form the classical Ag binding site. HCDR3 shows the greatest variability in terms of length and sequence, particularly in human Abs. Several crystal structures of Abs have demonstrated that human CDRs tend to adopt a limited number of canonical conformations, with the exception of HCDR3.⁷⁵ In each of the crystal

structures of human Abs complexed with Ags, HCDR3 has been shown to make important contacts in every case.^{23,401} Diverse CDR length and gene family usage have been shown to be essential features of immunological health and functional antiviral immune responses.^{153,228,389} Vaccinations that induce a broad Ab repertoire that is rich in CDR diversity are more likely to succeed than highly focused vaccinations inducing limited Ab repertoires. Although not universal, long HCDR3 regions are common in highly active Abs to HIV, and they may facilitate high-affinity binding to complex viral antigenic sites. For example, the crystal structure of the 17b mAb complexed with CD4-triggered HIV gp120 reveals a complex interaction that is accomplished only by the unique long HCDR3 region of this Ab.²³⁵ High-throughput screening for broadly reactive high-potency HIV-neutralizing Abs has isolated two unusual Abs with the longest CDRs ever identified,⁴⁴⁰ and the HCDR3s of these Abs possess fascinating secondary structural elements.³⁴⁶ In contrast, identification of another broadly neutralizing mAb specific for the CD4 binding site has a CDR3 loop of only 13 amino acids, although the variable region of the heavy chains is more than 30% somatically mutated from germ line.⁴⁵⁹

The Role of Isotype in Additional Mechanisms of Antibody-Mediated Virus Neutralization

The complement system is activated by the classical (Ab-dependent), alternative (Ab-independent), and lectin-binding pathways. Viral neutralization by specific Abs is concentration dependent and is often enhanced by complement activation. It has been reported that even apparently “nonneutralizing” Abs can acquire neutralizing activity with the addition of complement—for example, a nonneutralizing RSV murine mAb was shown to exhibit complement-enhanced neutralization *in vivo* in the presence of complement.⁹² Complement fixation is mediated by the C_H2 region of the Ab Fc domain of immunoglobulin M (IgM), IgG1, and IgG3 subclasses in humans and the IgM, IgG2a, and IgG2b subclasses in mice.³²⁸ Understanding the role of complement in enhancing the functional capacity of Abs to neutralize viruses has broad implications for vaccine design, because the cytokine milieu induced by infection or immunization affects the isotype and subclass of the Ab response to the viral Ags by activating selective promoters in the appropriate Ig heavy chain locus. B cells triggered in an environment with high IFN- γ concentrations tend to produce IgG1 and IgG3 Abs. In contrast, in the presence of a dominant IL4 response, B cells produce immunoglobulin E (IgE) and IgG4 Abs. IgE participates in allergic diseases, and it is generally considered desirable to avoid strong IgE responses following vaccination. The Fc region of Abs also mediates some cellular activities, termed *Ab-dependent cell-mediated cytotoxicity* (ADCC), which are discussed below.

Structural Features of Antigens Critical for Inducing Efficient Antibody Interactions

The conformation of epitopes on viral surface proteins often is critical to the ability of vaccine Ags to induce or bind neutralizing Abs. Most neutralizing Abs bind to conformationally dependent epitopes on surface proteins. Linear peptide vaccine candidates derived from the sequence of the natural Ag rarely recapitulate the conformation of the protective Ag, which

is why most peptide-based vaccines are poor immunogens for humoral immunity. Many subunit Ags comprising purified or recombinant viral proteins that have been developed as vaccine candidates contain the full polypeptide sequence of the Ag; however, the protein emerges from the purification process in a conformationally relaxed state that resembles the natural Ag only in part. Such Ags may induce high levels of Abs that bind the vaccine Ag but low levels of Abs that bind or neutralize virus.³⁸⁵ Some viruses appear to present highly antigenic surface loops to the immune system that are structurally non-essential, causing immune focusing on hypervariable domains of viral proteins, such as the influenza HA variable loops surrounding the sialic acid receptor-binding domain or the third variable (V3) region of HIV gp120. Recent studies, however, reveal that some subjects make broadly neutralizing Abs that recognize these hypervariable domains.¹⁵⁶ Many structurally critical domains of viral surface proteins are hidden from B cells because they are buried in the interior of viral molecules or oligomers of molecules, or they are exposed only briefly during rapid conformational changes required for virus attachment or virus–cell membrane fusion. For example, viral hydrophobic fusion peptides, receptor-binding domains, heptad repeats, and other critical regions of fusion proteins usually are not accessible to Abs. Most fusion proteins require cleavage by proteases before they are competent to fuse, and Abs to the precursor protein may not bind the cleaved protein in the mature virus particle.³³⁶ Posttranslational modifications of surface proteins, especially glycosylation, can present a challenge for Ab recognition of protein because of the highly varied nature of the glycoprotein population. Deglycosylated protein Ags may enhance induction of protein-specific Ags; however, these Abs may not efficiently recognize glycosylated proteins *in vivo*. Some virus-neutralizing Abs are directed specifically to carbohydrates on virus glycoproteins.⁵⁶ Some broadly neutralizing Abs to HIV, such as PG9 and PG16, recognize a conformational epitope that depends on glycosylation at specific variable loop N-linked sites.¹¹¹ Posttranslational modification of Abs also can affect the interaction of Ab and virus. For instance, several human Abs to HIV gp120 are sulfated in the combining site, which allows the Ag-combining sites to mimic the structure of the virus coreceptor CCR5, which is sulfated.⁷⁴ These Abs inhibit infectivity by binding to the co-receptor-binding domain on HIV gp120.

Antibody Escape Mechanisms

Viruses, especially RNA viruses with error-prone RNA-dependent RNA polymerases, exhibit facility in generating genetic diversity during multiple replicative cycles. During chronic infections, such as those with HBV, HCV, or retroviruses such as HIV, viruses that accumulate amino acid changes in epitopes that are targets of Abs owing to point missense mutations in the corresponding genes can escape neutralization by reduction or loss of binding. Some viruses easily shed surface glycoproteins (e.g., HIV gp120 or Ebola GP)¹⁸⁷ or encode soluble forms of surface glycoproteins using alternative start codons (e.g., RSV G protein),³⁶⁹ in part as a decoy mechanism, targeting Abs away from infectious virions. The immunity induced by experimental vaccine candidates that are narrowly targeted to single epitopes or single proteins are susceptible to rapid viral escape. To avoid such Ab-resistant mutants, optimal vaccines should induce broad humoral responses to a diversity of antigenic sites.

Antibodies Active Against Virus-Infected Cells

Viruses that mature at the cell surface by budding or that insert viral glycoprotein(s) into the cell surface membrane render the infected cell susceptible to lysis by Ab-dependent complement-mediated lysis or ADCC mechanisms. This lysis is mediated by cytolytic cells, including NK cells, neutrophils, and eosinophils, in an Fc region-dependent manner. Ab-dependent cell-mediated virus inhibition (ADCVI) activity is similar but is typically measured with a readout of reduction of virus replication instead of lysis of target cells. Cytophilic Abs can arm leukocytes in the ADCC reaction, which has been shown to be important in the resistance of infant mice to herpes infection and for clearance of a retrovirus.^{87,226} Fc receptor-mediated mechanisms appear important to neutralization of HIV.¹⁹¹ Some herpesviruses encode an IgG Fc receptor homolog, which enables the virus to evade ADCC by binding Abs, especially virus-specific Abs if they bind virus proteins on infected cells, suggesting the importance of the ADCC effector or other Fc-mediated mechanisms *in vivo*.¹¹⁵ RSV ADCC activity mediated by NK cells has been detected in monkey or human peripheral blood using Abs in serum.^{216,277,395} Because infection of cells must occur for these immune mechanisms to act, these mechanisms represent a second line of defense against infection or disease.

Inadvertent Induction of Antibodies to Host Antigens

Immunization of monkeys with formalin-inactivated SIV produced in human cells induced Abs directed at Ags originating from the cells used to produce the virus.⁴⁰⁷ These anticellular Abs can neutralize the infectivity of SIV produced in human cells, although not virus produced in monkey cells, by interacting with human Ags incorporated into the virion outer membrane. This form of neutralization, which is mediated by complement-mediated virolysis, can yield an overestimate of vaccine immunogenicity. Hence, an effort should be made to avoid immunization with virions into which foreign host cell Ags have become incorporated.⁴⁰⁷ In some cases, even the native virion proteins may mimic structures associated with host cell proteins. For example, many of the original broadly neutralizing mAbs specific for the HIV-1 gp160 envelope glycoprotein have been shown to cross-react with host cell proteins.¹⁹⁰

Inhibitory Antibodies That Lack Classical *In Vitro* Neutralizing Activity

Some Abs that do not exhibit neutralizing activity *in vitro* can mediate resistance to virus infections, although typically they are less effective than neutralizing Abs.²⁹⁷ Such Abs can be directed against Ags on the surface of virus particles or against virion or nonstructural proteins displayed on the surface of infected cells. *In vivo*, these Abs mediate antiviral activities by several different mechanisms. First, virus particles coated with nonneutralizing Abs can undergo accelerated clearance from the bloodstream. Second, Abs directed at surface glycoproteins such as the NA of influenza A virus or the HA-esterase protein of coronavirus (CoV) can decrease the level of virus replication in the target organ, presumably by inhibiting the release of virus from infected cells.^{46,466} Third, Abs can lyse virus-infected cells via IgG Fc-dependent mechanisms.^{92,391}

Antiviral Activity of Antibodies *In Vivo*

Resolution of infection generally depends on CTLs, which reduce infection by lysing virus-infected cells. However, virus-specific Abs also can exert a therapeutic effect. Dramatic clinical therapeutic effect of viral Abs has been observed in patients with Argentine hemorrhagic fever, which is caused by Junin virus (an arenavirus). This disease has a high mortality; however, death can be prevented with a preparation of pooled human serum with a high titer of Junin virus-neutralizing Abs administered within 8 days of onset of symptoms.^{123,261} Mucosal virus infections that are limited to the cells that line the lumen of the respiratory tract also can be cleared by specific Abs that are delivered by parenteral inoculation or by direct instillation into the lungs. RSV immune globulin or RSV-neutralizing Abs protect against severe lower respiratory tract disease.^{1,2} These Abs also reduce established infection in animal models; however, therapeutic trials in humans have not revealed a clinical benefit of treatment of active infection. Influenza A virus HA-specific IgG Abs cleared the lungs of influenza-infected SCID mice in the absence of other recognized immune functions.³³⁴ Abs can exert a therapeutic effect in privileged sites where CD8 CTLs are not active. Central nervous system (CNS) neurons are not good targets for CD8 CTLs, because they have highly regulated expression of class I MHC glycoproteins. Nevertheless, in SCID mice, persistent infection of brain neurons by the alphavirus Sindbis virus can be cleared rapidly by parenteral inoculation of envelope-glycoprotein-specific Abs without causing obvious cell damage.²⁴⁸ Some patients with underlying X-linked agammaglobulinemia complicated by chronic enteroviral meningoencephalitis have been treated successfully with human IgG that contains Abs specific for the infecting virus. A therapeutic effect was achieved with IgG administered by the intravenous or intraventricular routes.^{118,275} Failure of human IgG to alter chronic enteroviral meningoencephalitis in some patients suggests that the concentration of enterovirus-specific Abs in human IgG is often inadequate.

Mucosal Antibodies

Abs have been shown to function within mucosal epithelium.^{268,269} Dimeric immunoglobulin A (IgA) secreted at the basolateral surface of cells or from plasma is transcytosed to the apical surface in association with polymeric Ig receptor to which dimeric IgA with J chain binds. During transcytosis through cells infected with the Sendai virus, virus-specific IgA can reduce intracellular virus and infectivity. The mechanism responsible for this effect is not clear, although it is possible that the endocytic pathway used for IgA transport and the exocytic pathways used for transport of viral glycoproteins intersect at some location within the cell, possibly the apical recycling endosome.¹⁴² Similar studies with IgA Abs to rotavirus and measles virus suggest that IgA molecules may inhibit viruses inside epithelial cells or after transcytosis.^{50,463} Induced IgA molecules to HIV gp41 appear to block transcytosis across genital epithelial surfaces.⁴² The FcRn receptor for IgG also is present in some epithelial cells and could participate in transport or retention of IgG at mucosal surfaces.

Abs present in the systemic circulation efficiently protect internal organs against viruses that are introduced directly into the bloodstream (e.g., HBV and HIV) or that spread via the bloodstream from primary sites of replication such as the respiratory or gastrointestinal mucosa. As mentioned previously,

diseases produced by viruses that fall into the latter category (i.e., measles, polio, hepatitis A, rubella, smallpox, and varicella) can be prevented or modified by Ig prophylaxis, often with small amounts of Ab that are difficult to detect in the blood of recipients. Such Abs are relatively easy to induce by parenteral immunization with live or inactivated virus vaccines. In contrast, Abs present in the systemic circulation do not provide efficient protection against viral diseases that are limited to mucosal surfaces unless these Abs are present in high titer. This is because only a small proportion of such Ig molecules traffic from the plasma to the luminal surface of the mucosal epithelium by transudation. Therefore, to prevent viral diseases that are limited to mucosal tissue, two different strategies can be employed. The first is to induce Abs such as secretory IgA at the mucosal site by virus replication or immunization at that site. The second, and less efficient, strategy is to stimulate a high titer of serum IgG Abs that can protect mucosal surfaces following transudation.

When IgG Abs present in the blood are passively transferred to mucosal surfaces by transudation where they can exert antiviral activity, there is a gradient regarding the ability of serum IgG-derived Abs to restrict virus replication on mucosal surfaces. This gradient is less in lung than it is in the nasopharynx. IgG Abs, if present in the serum in high enough titer, can provide almost complete resistance to pulmonary replication of RSV; however, resistance in the upper respiratory tract is more difficult to achieve. Transudation of IgG also probably occurs in the intestine, especially in inflammatory states, although IgG is more easily subjected to proteolytic degradation in the intestinal lumen than in the respiratory tract. Immunization of the female genital tract with a live virus vaccine can induce the local synthesis of IgG antiviral Abs such that the specific activity of mucosal IgG Abs significantly exceeds that of serum, indicating that IgG Abs present on a mucosal surface can come either from serum via transudation or from IgG Ab-secreting cells present in the submucosal tissues.³⁴⁰ Although passively transferred IgG Abs can provide mucosal immunity in the lower respiratory tract, the major mediators of resistance to virus infection of the upper respiratory tract, the larger airways of the lungs, and the gastrointestinal tract are mucosal Abs, many of which are IgAs selectively transported across mucosal surfaces to exert antiviral effects on the luminal surface. Both nonneutralizing⁵⁰ and neutralizing³⁷⁹ IgA Abs have antiviral effects on mucosal surfaces, with the former active intracellularly during transcytosis and the latter active both intracellularly and on the luminal side of the epithelium. Antiviral IgA Abs function to clear virus infections, to modify the severity of disease on reinfection, and to prevent infection on re-exposure to virus. The level of antiviral IgA Abs, as well as the number of virus-specific IgA-secreting cells, often correlates with resistance to virus infection.^{83,469} The advantages of IgAs in the mucosal fluids are that they are transported more efficiently, they resist proteolytic degradation better than IgG, and the dimeric nature of secretory IgA enhances avidity.

The primary mucosal IgA response peaks within the first 6 weeks after infection and usually decreases to a low, often barely detectable, level by 3 months. The transient nature of the primary mucosal Ab response is a factor in the ability of many viruses to reinfect mucosal surfaces and underlies the need for two or more doses of vaccine to efficiently immunize mucosal surfaces. The virus-specific IgA Ab response is greater

at the site of virus replication or of Ag administration than at distal sites, suggesting that mucosal immunity is best induced by antigenic stimulation of sites directly involved in replication of the wild-type virus.

Adverse Effects of Antibodies

Abs can contribute to the potentiation of disease. For example, heterotypic Abs to the envelope glycoprotein of dengue virus appear to play a role in the severe clinical entity known as dengue hemorrhagic fever/shock syndrome.²³¹ Dengue viruses replicate primarily in cells of the mononuclear phagocyte lineage, and subneutralizing amounts of dengue virus Abs enhance dengue virus infection of these cells *in vitro* by increasing uptake of virus via IgG Fc receptors present on these cells.¹⁸⁰ However, the mechanism by which augmented disease results from enhanced access of dengue virus into mononuclear cells remains unclear.³⁷⁷ Immune complexes were detected in the lung tissues of fatal cases of influenza during the 1957 and 2009 pandemics, suggesting a potential role for enhancing Abs in severe influenza disease.²⁸⁷

OBSTACLES TO IMMUNIZATION IN EARLY LIFE AND IN THE ELDERLY

Immunization of Infants

The developmental immaturity of the immune response to viruses in the very young is seen clearly in the difficulty to immunize neonates and infants.⁴⁰² Young infants are a preferred target population for immunization, because most children present to health systems with the highest frequency at birth or shortly after. A high level of access to infants allows universal immunization, and many viral diseases are most severe early in life. Many obstacles arise, however, in attempts to immunize infants in the first several weeks or months of life against disease caused by viruses.

First, most infants possess maternal Abs that can interfere with response to infection or the infectivity or immunogenicity of primary immunization. Live attenuated measles virus cannot be given effectively prior to 1 year of age, because many infants possess maternal Abs until that time that reduce or eliminate immunogenicity of the vaccine.¹⁰ Ab-mediated suppression can be overcome in some instances by increasing the dose of the vaccine—for example, the inactivated hepatitis A vaccine or a replicating influenza vaccine.^{84,101} The immune suppression by maternal Abs is more potent against B-cell responses than against induction of virus-specific T cells, possibly because the Ab response generally depends more on Ag dose than T-cell responses.⁹⁷

Second, the ability to respond to viral surface proteins with a protective Ab response is acquired gradually over the first year of life, reflecting developmental maturation of the neonatal immune system. Responses of seronegative infants to live measles vaccine remain relatively poor during the second 6 months of life.¹⁴⁴ Responses to live VZV vaccine also are reduced in the first year of life.⁴³⁶ The youngest infants mount Ab responses to experimental mucosal immunization with live influenza, RSV, or parainfluenza virus vaccines that are low in magnitude, quality, and durability.^{84,213,214} The molecular and cellular basis for immunological immaturity is not fully defined. Infant virus-specific Ab sequences are characterized

by marked lack of somatic mutations, resulting in low-affinity Abs of low function.⁴⁴⁸ Infant B cells exhibit limited capability to switch isotype from IgM to IgG2 Abs, and the isotype profile of circulating Abs differs from adults until age 5 to 6 years. Infants possess reduced levels of some components of the complement cascade, especially C8 and C9 that participate in membrane attack complexes, leading to impaired complement-mediated reactions. Infants exhibit a high proportion of transitional immature B cells and poor organization of the splenic marginal zone.

The Ab responses that young infants make to respiratory virus surface glycoproteins are significantly lower in quality than those of adults. Studies have described a dissociation of the level of neutralizing and binding Abs in the very young infant.⁴⁵⁷ This dissociation may be of functional significance, because neutralizing Ab titers correlate well with protective efficacy in studies of protection for viruses. Dissociation between neutralizing and binding Abs also characterized the serum Abs induced by the ill-fated formalin-inactivated RSV experimental vaccine of the 1960s and probably accounts for the lack of protective efficacy of Abs induced by that vaccine candidate.³⁰¹ Ab responses induced by infections of infants are less durable than those of older subjects. Postinfection serum Ab levels to respiratory viruses often wane significantly several months after primary infection, especially if infection occurs at a very young age. Animal models suggest that B-cell priming occurs effectively early in life or in the presence of suppressive Abs^{96,97}; however, the deficient maintenance of long-lived plasma cells in the bone marrow may lead to rapid waning of humoral immunity.³⁴⁹ Reduced humoral immunity to vaccines early in life also may reflect reduced T-helper cell function and altered dendritic cell function. Neonatal CD4 T cells exhibit reduced ability to secrete IFN- γ , reflecting limited secretion of IFN- α and IL-12 by dendritic cells.^{106,155}

Immunization of the Elderly

Obstacles to effective immunization also arise late in life owing to immune senescence. Immune senescence in the elderly is marked by a decrease in the magnitude, quality, and duration of Ab responses and a reduction in functional T cells, especially CD8 T cells. Elderly T cells are distinguished by alterations in cytokine production, co-stimulatory molecule expression, susceptibility to apoptosis, and changes in the level of DNA damage and repair and telomerase length.¹⁴⁵ Chronic virus infection may contribute to immune senescence. For example, CMV-specific T cells progress to a differentiated state in the elderly owing to chronic antigenic stimulation.³⁴⁴ This syndrome has been described as an immune risk phenotype in the elderly, reflecting the accumulation of a high percentage of circulating CMV-specific CD8 T cells at a terminal stage of differentiation that may detract from the flexibility of the T-cell repertoire to respond to other Ags. The CD4 T-cell responses of healthy elderly individuals appear to sustain a good level of function until late in life. Waning immunity to latent viruses may be boosted in the elderly in some cases. Immunization of the elderly with live attenuated varicella virus vaccine reduces the incidence of shingles in that population.³³³

Aging has varying effects on the response to different Ags. For example, the immunogenicity of recombinant hepatitis B vaccine is reduced starting in the fifth decade and is poor in

the elderly.⁴⁵⁵ Ab responses to influenza virus vaccine also are reduced in the elderly. Practically speaking, however, although vaccination in the elderly may be reduced in efficacy and may require frequent boosters or other alterations in strategy, the effectiveness of many vaccines such as influenza virus vaccine are reasonable enough to support vaccination of this group. It also may be possible to improve the immune responses in the elderly by utilizing adjuvants or alternative vaccination strategies. Investigational gene-based vaccines have been shown to be highly immunogenic in older adults compared to the typical age-related decrease in responses seen with many traditional vaccines.²⁴³

GOALS OF IMMUNIZATION AGAINST VIRAL DISEASES

Prevention

The major goals of immunization against viruses are the prevention or modification of disease in an individual and the control of epidemic infection within populations. Most viral vaccines prevent or modify disease without necessarily preventing infection. The ways in which this objective is achieved are diverse. Whereas most viral vaccines are administered before infection occurs, prevention of CNS disease in individuals inoculated with rabies virus by an animal bite can be achieved by administration of a vaccine regimen initiated shortly after infection has occurred. This postexposure prophylaxis is possible because the long incubation period of the infection permits the development of an effective immune response in time to modify infection and prevent disease. Interestingly, even for viruses with a more rapid course, such as variola, individuals can be protected against a fatal outcome if vaccinia virus vaccine is administered up to 4 days after the initial exposure to the virus. This effect may be attributable to augmented innate immune responses or more rapid induction of adaptive immune responses.

The major goal of immunization against rubella virus is the prevention of fetal abnormalities caused by intra-uterine infection. To achieve this goal, both males and females are immunized in the United States. Immunization of males has little direct benefit to the vaccinee other than prevention of the relatively mild illness caused by the rubella virus, and males are not targeted in all national vaccine programs. The fetus of a vaccinated female is protected by immunization of the mother before pregnancy. Herd immunity resulting from extensive immunization of males and females provides some protection to the fetus of an unvaccinated female by decreasing the circulation of virus in the community. An example of herd immunity was seen early after introducing the mumps vaccine. The incidence of mumps declined precipitously before vaccine coverage was significantly expanded. A modest reduction in the number of susceptible persons and transmitters had a significant impact on the epidemic (Fig. 14.2) and e-Fig. 14.2.

In addition to reducing the frequency of susceptible persons and transmitters, some live viral vaccines can improve herd immunity by the spread of vaccine from recipients to contacts. This phenomenon has been observed with oral live poliovirus vaccine³⁸³ resulting in the indirect immunization of a significant proportion of the population and a marked reduction in the incidence of poliomyelitis in both vaccinated and “unvaccinated”

FIGURE 14.2. Incidence of mumps in the United States after introduction of vaccine. The number of mumps cases in the United States began diminishing shortly after the introduction of the vaccine. This effect is considered to be an example of herd immunity, because vaccine distribution and coverage was less than 50% for about 10 years and was not a formal recommendation in the United States until 1976. (Adapted from Cochi SL, Preblud SR, Orenstein WA. Perspectives on the relative resurgence of mumps in the United States. *Am J Dis Child* 1988;142(5):499–507.) Also see e-Fig. 14.2.

individuals. Spread of vaccine virus has been viewed by many as a desirable property because this transmission confers the benefits of immunization on many individuals who were not vaccinated. However, spread of vaccine in the population also raises concern because of the rare occurrence of vaccine-associated paralytic disease among contacts of vaccinees, and immunization of persons without their prior consent presents ethical issues.

Although most vaccines in use today are effective in preventing disease, they usually are inefficient at completely preventing infection. Prevention of infection is a desirable property for specific vaccines such as HBV and HIV. Infection with HBV during the neonatal period is associated with an increased risk of progression to the chronic carrier state and associated with the development of chronic liver disease and hepatocellular carcinoma later in life. Therefore, a major goal of HBV vaccination is to prevent transmission of infection from persistently infected mothers to their infants during the neonatal period. Considerable success in this effort has been achieved through the use of hepatitis B surface antigen (HBsAg) vaccine or hyper-immune HBV antiserum plus vaccine immediately after delivery.¹⁹⁵ HIV is a lentivirus, and the possibility of progression to AIDS can occur many years after initial infection. Therefore, it is desirable to develop a vaccine that induces immunity to prevent infection or result in an abortive or transient HIV infection.

The vaccine for HPV was licensed based on its ability to prevent cervical neoplasia.⁴ In addition to preventing the acute effects of virus infection, the HBV vaccine is also given with the goal of preventing hepatomas.¹⁹⁵

Immunotherapy

Herpes simplex virus type 1 (HSV-1) or type 2 (HSV-2) and VZV produce latent infections in sensory ganglia that periodically reactivate, resulting in development of new lesions and increased opportunity for transmission of virus. Therefore, a goal of immunization of persons previously infected with these viruses is to prevent or ameliorate recurrent disease caused by reactivation of their latent infection.³⁵ This form of immunization is referred to as immunotherapy. Other illnesses that are candidates for immunotherapeutic vaccines include warts and cancer caused by HPV and chronic hepatitis caused by HBV or HCV. HIV-1 has also been considered

as a target for immunotherapy to prevent the long-term consequences of chronic infection or to reduce the requirements for ongoing antiretroviral drug therapy. Because of the extent of repeated Ag exposure and damage to many elements of the adaptive immune system, it may be difficult to elicit new immune responses to effectively control virus.⁶² Effective immunotherapeutic vaccines for recurrent HSV face a similar challenge because the vaccinees previously infected by wild-type virus are repeatedly reimmunized during each recurrence. However, for a related herpesvirus, VZV, where recurrence is relatively uncommon, immunization with live attenuated vaccine reduces the incidence of herpes zoster and postherpetic neuralgia.³³³

Eradication or Elimination

Appropriate use of a highly effective vaccine can help to eradicate a major disease when humans are the only natural host for the virus and there is no natural reservoir or intermediate host. During the 1970s, this goal of eradication was achieved for smallpox largely through the use of live vaccinia virus vaccine. This campaign ranks as one of the major public health achievements in all history. Two other human viruses have been targeted similarly for eradication, namely poliovirus and measles virus, and significant progress toward these goals has been made for both viral pathogens. The United Nations officially declared eradication of the morbillivirus animal pathogen rinderpest in 2011, after a concerted worldwide eradication program. Unfortunately, eradication of viral pathogens usually is an elusive goal because of setbacks from social instability, anti-vaccine sentiments, the threat of bioterrorism, and the potential for intentional reintroduction or resurgence of previously eradicated viral pathogens. Therefore, it will be prudent to find ways of maintaining immunity to serious virus pathogens even after eradication of virus in the natural reservoir has been achieved. The new technologies that have improved our ability to identify emerging pathogens and to develop biologics for vaccines and therapeutics have also created an intellectual reservoir that is a formidable barrier to true eradication efforts. Elimination of a virus pathogen suggests that epidemic and endemic disease is controlled and no active cases are present. However, setting the goal of elimination acknowledges the possibility of re-emergence and would include maintenance of active vaccine-induced immunity.

HISTORY OF VIRAL VACCINE DEVELOPMENT AND FUTURE PROSPECTS

The history of discovery and development for each viral vaccine is unique and instructional. Although space limitations prevent the full description of each vaccine, some of the major events are outlined. Although each vaccine development story is different, there are common events and themes that have been catalogued in a supplementary table (e-Table 14.1) that includes (a) disease description and virus discovery, (b) vaccine

discovery and/or proof of concept, (c) vaccine licensure or first human use, and (d) unique or unanticipated events.

Origins of Vaccinology

Origin of Live Virus Vaccination

Most viral vaccines were developed as a result of both fortuitous events and empirical findings. The origin of modern vaccinology, and particularly live virus vaccination, is based on the practice of variolization (mechanical attenuation and

FIGURE 14.3. Origins of live attenuated viral vaccines. **A:** Edward Jenner is credited for performing the first vaccine experiment in which he demonstrated that inoculation of a boy with purulent material obtained from a cowpox lesion on the hand of a milkmaid protected him against subsequent challenge with variola. This event launched the formal concept of vaccination and established the prototypical approach for developing live attenuated viral vaccines. **B:** The implementation of smallpox vaccination faced many of the same issues of fear and misunderstanding that are prevalent today and impede the deployment of effective vaccines, as illustrated by a political cartoon published in 1804. **C:** The successful eradication of smallpox yielded many lessons about the value of simple, low-cost, local production of vaccine, as illustrated by the collection of vaccine material from the hide of a cow during the initial phases of the World Health Organization–sponsored eradication campaign. There were also lessons on the importance of product stability and simple delivery approaches. **D:** Once vaccinia was lyophilized, it could be reconstituted on site and was not as dependent on maintenance of the cold chain. The bifurcated needle (**D**) was an innovation that provided a simple standardized approach to inoculation without the need for needles or mechanical devices and allowed vaccination to penetrate remote locations. (**A** and **B**, courtesy of the National Library of Medicine; **C**, courtesy of J. Mohr, World Health Organization; **D**, courtesy of James Gathany/Centers for Disease Control and Prevention.)

intentional low-dose infection) to reduce the virulence of subsequent smallpox infection, which was initiated more than 1,000 years ago in India and China. From this arose the concept of vaccination (using an alternative agent to provide immunity against an infectious disease) and the first vaccine used in humans—live cowpox virus. In 1796, Edward Jenner inoculated 8-year old James Phipps with purulent material taken from a cowpox pustule on the hand of milkmaid Sarah Nelmes and introduced it into an incision on the boy's arm. Jenner subsequently proved that the boy was protected from an inoculation of material from a smallpox lesion. He published the work in 1798 and coined the word *vaccine* from the Latin *vacca* for cow, designating the process vaccination. For 80 years, live virus was transferred almost exclusively from human arm to arm by collection of purulent material. Subsequently, vaccine was propagated on the skin of calves using serial inoculation, resulting in vaccinia virus as the distinct vaccine strain.²⁶⁰ This vaccine was used successfully to eradicate smallpox from the population, and smallpox remains the only human virus infection to be eradicated through a vaccination campaign (Fig. 14.3).

Origin of Inactivated Virus Vaccination

In the 1880s, Louis Pasteur and his colleagues attributed rabies to virus replication to the CNS. Next, they discovered that drying rabies-infected tissue at room temperature attenuated the infectivity of the tissue. The dried rabies-infected tissue was determined to be noninfectious, although serial inoculation of dogs with the tissues provided protection against an otherwise lethal rabies virus challenge. Inoculation of dried rabies-infected CNS tissue was tested in a single human postexposure case in 1885 when Pasteur serially inoculated Joseph Meister, a 9-year-old boy bitten by a rabid dog more than 2 days earlier. The initial inoculations contained highly attenuated virus from rabbit spinal cord dried for 15 days, followed by inoculations with less attenuated virus-infected tissue. In total, the regimen included 13 immunizations over 10 days. The boy was fully protected from disease, representing the beginning of an era in which inactivated vaccines were used for other viral diseases following Pasteur's paradigm of identification, inactivation, and inoculation (Fig. 14.4) and e-Table 14.1.

Critical Events in the History of Viral Vaccines

Since the introduction of vaccinia virus (Chapters 66 and 67), licensed vaccines have been developed for 15 other viral pathogens (Table 14.1). Notable advances in viral vaccine development over the past century include semieradication of many virus infections; processes for optimization of manufacturing cell lines for next-generation vaccines; utilization of human immune correlates to establish efficacy for licensure; and improvements in vaccine safety monitoring, which is important for public safety but also serves to keep safe and efficacious vaccines from unwarranted negative assessment.

Semieradication Secondary to Effective Vaccine Campaigns

Several vaccines have resulted in regional semieradication of virus disease or dramatic reduction in the incidence or morbidity from infection (polio, measles, mumps, rubella, rabies, and VZV). Other vaccines are highly effective and have been reduced to use only for travelers to endemic areas of the world

FIGURE 14.4. Origins of inactivated viral vaccines. Louis Pasteur is pictured here as the person responsible for the inactivated viral vaccine concept. His work on the rabies vaccine produced by desiccation of spinal cords from rabid dogs also anticipated the public debates that still occur involving the balance of risk and benefit to the individual and the public from the implementation of vaccines. (Courtesy of the National Library of Medicine.)

(yellow fever, Japanese encephalitis). Licensed vaccines for influenza and hepatitis A and B are highly effective, and their impact on frequency of infection has been improved by new strategies for distribution (Table 14.2).

Modernization of Vaccine Manufacturing

The process of manufacturing a vaccine is complex, and the primary cornerstone in overall production is the substrate used for vaccine growth or antigen production. Early-generation vaccines were often grown in animal organ cells, including adenovirus vaccine in monkey kidney cells and Japanese encephalitis virus (JEV) vaccine in mouse brains. During the second half of the 20th century, modernization of vaccine production included the progression to use of cell lines as substrates, including current JEV vaccine in Vero cells and hepatitis B vaccine in yeast. Influenza vaccine researchers continue to develop U.S. marketed vaccines using chicken eggs as the substrate but have developed cell culture–based substrates that are used effectively in some European countries. The transition to cell-based substrates offers a more efficient, more reliable, and more stable manufacturing process.

Surrogate End Points for Vaccine Efficacy

Traditionally, the assessment of vaccine efficacy has been made by determining whether infection or disease has been

TABLE 14.1 Viral Vaccines Licensed in the United States^a

Virus vaccine	Number of serotypes covered by vaccine	Type of vaccine			Target population	Comments
		Live	Inactivated	VLP		
Adenovirus ^b	2 (types 4 & 7)	+			Military recruits	WT virus in enteric-coated capsules orally to selectively infect the gut; lapse in manufacturing
Hepatitis A	1		+		Travelers, healthcare workers	IM; 2 doses; combined hepatitis A & B vaccine also available
Hepatitis B	1			+	All children	IM or SQ; 3 doses
Human papillomavirus	4 (types 6, 11, 16, & 18)			+	Preteen girls	IM to prevent cervical cancer; 3 doses
Influenza A & B	3 (H1N1, H3N2, & type B)	+	+		Elderly, patients with cardiopulmonary disease, school-age children, others	IM or ID; repeated annually with disrupted virus vaccine, or intranasal delivery of live attenuated vaccine
Japanese encephalitis	1		+		Travelers to endemic region	IM; single dose
Measles	1	+			All children	IM or SQ; single dose; booster recommended at 4–6 y of age
Mumps	1	+			All children	IM or SQ; single dose; booster recommended at 4–6 y of age
Poliovirus	3	+	+		All children	IM or SQ; 3 doses of inactivated vaccine recommended in United States; booster recommended at 4–6 y of age
Rabies	1		+		High-risk or exposed persons	IM; prophylactic 3 doses; therapeutic 4 doses
Rotavirus ^b	4 (G1, G2, G3, & G4)	+			All children	Oral vaccine based on rhesus rotavirus; 3 doses; removed from market because of concerns related to intussusception
	5 (G1, G2, G3, G4, & P[8])	+			All children	Oral vaccine; 3 doses; must start prior to 3 mo of age
	1 (G1P[8])	+			All children	Oral vaccine; 2 doses given at 2 & 4 mo of age
Rubella	1	+			All children	IM or SQ; single dose; booster recommended at 4–6 y of age
Smallpox	1	+			Military & first responder healthcare workers; recommended for laboratory workers using recombinant vaccinia virus	Intradermal vaccine used to eradicate smallpox
Varicella	1	+			All children; the elderly to diminish herpes zoster	IM or SQ; single dose; booster recommended at 4–6 y of age
Yellow fever	1	+	Travelers to endemic region	IM, single dose		
Total number of viruses covered	27	19	9	5		

VLP, virus-like particle; WT, wild-type; IM, intramuscular; SQ, subcutaneous; ID, intradermal.

^aSee individual chapters for specifics on target populations and immunization schedules for individual agents, which may vary or change from this overview. In addition, see the following website for a list of licensed vaccine products, including combination products: <http://www.fda.gov/cber/vaccine/licvacc.htm>.

^bRotaShield tetravalent vaccine is no longer available. RotaTeg pentavalent and Rotarix monovalent vaccines are available.

TABLE 14.2 Impact of Licensed Vaccines on Viral Diseases With Well-Defined Surveillance and Estimated Impact on Disease Burden for Other Viral Vaccines

Viral disease	Year of peak U.S. prevalence	Peak number of cases per year in U.S.	Number of annual U.S. cases in modern vaccine era
Impact of licensed vaccines on viral diseases with well-defined surveillance			
Hepatitis A	1971	59,606	1,670 ^a
Hepatitis B	1985	26,654	3,374 ^a
Measles	1958–1962	503,282	63 ^a
Mumps	1967	185,691	2,612 ^a
Polio	1951–1954	16,316	0 ^a
Rubella	1966–1968	47,745	5 ^a
Congenital rubella	1966–1968	823	0 ^a
Smallpox	1900–1904	48,164	0 ^a
Estimated impact on disease burden for other viral vaccines			
Influenza A & B	Annual epidemics	~50,000 excess deaths per year ^b	Reduces morbidity & mortality; however, effectiveness varies from year to year because of variations in circulating virus strains
Japanese encephalitis	—	—	Only necessary for travel to endemic regions, highly effective
Rabies	<1940	>100 deaths/y	2–3/y ^c
Varicella	<1994	>4 million/y	Vaccine offers 83%–96% efficacy against primary infection ^d
Yellow fever	1905 ^e	8,399	Only necessary for travel to endemic regions, highly effective

^a<http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5953a1.htm>.^b<http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5933a1.htm>.^c<http://www.cdc.gov/rabies/location/usa/surveillance/index.html>.^dhttp://www.merck.com/product/usa/pi_circulars/v/varivax/varivax_pi.pdf.^eLast U.S. epidemic in New Orleans.

prevented. In the process of establishing vaccine efficacy, the use of a human immune correlate of protection is potentially more efficient and has been implemented successfully in the yearly approval process for influenza vaccines. Influenza vaccines typically are approved based on the accepted surrogate of protection, a hemagglutination inhibition (HAI) titer of 1:40 or higher or a fourfold increase over the prevaccination HAI titer. In this case, the immune response serves as a surrogate marker that is predetermined to predict clinical benefit; therefore, the more lengthy process of assessing the presence or absence of influenza infection in a clinical trial is not always needed (<http://www.fda.gov/BiologicsBloodVaccines/GuidanceComplianceRegulatoryInformation/Guidances/Vaccines/ucm074794.htm>). Similarly, assessing the end result of infection (or absence of) rather than documenting an effect on the virus itself can also be used to assess protective efficacy. HPV vaccines were licensed based on efficacy derived from the prevention of cervical and vulvar cancer, precancerous lesions, and dysplastic lesions (<http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm111283.htm>).

Maintaining Vaccine Availability

Vaccine efficacy, need, utilization, and safety (or perceived safety) all have a significant impact on the success of licensure and sustained availability of a vaccine. Two licensed vaccines that are no longer available are the adenovirus serotypes 4 and 7 and the tetravalent rhesus rotavirus vaccine. Production of the

adenovirus vaccine, selectively given to new military recruits, was stopped by the sole manufacturer in 1995 for economic reasons. Since then, morbidity from adenovirus infections has increased among military recruits, and epidemics have occurred in training centers.¹⁶⁹ In addition to economic concerns, safety concerns have also prompted an abrupt end to the use of vaccines. Specifically, RotaShield, a live tetravalent rhesus rotavirus reassortant vaccine against the four major prevalent serotypes (based on VP7, a major outer capsid glycoprotein), was effective but was later withdrawn from market. A postmarketing analysis revealed that the vaccine was associated with an excess rate of intussusception of up to 1 per 2,500 vaccinees that occurred in the immediate postvaccination period, predominantly following the first dose of vaccine.³⁰⁶ Following withdrawal of RotaShield, subsequent studies led to a significant downward revision of these estimates and have suggested that the early period of increase in intussusception seen after the first dose was followed by a period of compensatory decrease such that there was no net overall increase in the number of cases in vaccinees less than 1 year of age.³⁰⁶ Furthermore, the excess cases of intussusception occurred mostly when the vaccine was used in children 3 months of age or older to “catch up” rather than in vaccinees who received the ideally recommended schedule of 2, 4, and 6 months of age.^{212,403} This case highlights the importance of the analysis of postmarketing data, which needs to be especially thorough and comprehensive because it can dramatically impact the availability of a vaccine that may otherwise have a

favorable risk/benefit ratio. Despite the initial conclusions and withdrawal of RotaShield from the market, two newer versions of a rotavirus vaccine have been developed. Pentavalent RotaTeq has been licensed in the United States for infants less than 3 months of age. It consists of a mixture of live attenuated, bovine/human reassortant viruses that express a single VP4 (P1A) as well as VP7 (G) Ag from G1 through G4 strains of rotavirus and VP4 (P1A[8]). P1A is the most common VP4 in G1, G3, and G4 strains and is present in a major portion of G9 viruses that are becoming more prevalent in some regions. The second new vaccine is a monovalent VP7 G1:P1A[8] attenuated human rotavirus strain that was first licensed in Mexico and the Dominican Republic¹⁵¹ and later in 2008 in the United States. These two vaccines protect against severe gastroenteritis attributable to rotavirus. Large-scale postlicensure evaluations will be essential to more clearly elucidate the overall risks associated with rotavirus vaccines in the general population.

Future Directions in Vaccinology

In recent decades, major advances in viral vaccine development have coincided with the emergence of new technologies (Fig. 14.5). Therefore, selected technologies that are likely to influence future vaccine design are discussed briefly.

Impact of Advances in High-Throughput Sequencing Technology

The Human Genome Project stimulated major investments in sequencing technology, resulting in breakthroughs that have increased throughput by orders of magnitude. As a result, it is now feasible to sequence all nucleic acids in samples of interest, such as vaccine preparations. Not surprisingly, such experiments have identified previously unidentified agents or nucleic acids in licensed vaccines, such as porcine circovirus type 1 (PCV1) in the commercial rotavirus vaccine Rotarix.⁴³⁸ The U.S. Food and Drug Administration (FDA) temporarily suspended use of the vaccine in 2010; however, experts agreed

that this highly prevalent nonpathogenic pig virus does not infect humans, and the use of vaccine was reinstituted. Some vaccines are produced in avian or primate cell lines, and thus it was not surprising that RNAs from avian leukosis virus, which is noninfectious for humans, or genetically defective DNAs from simian retrovirus (SRV) were present in products of such cell lines. Another interesting finding of such sequencing efforts is that the vaccine virus populations contain minority variants with polymorphisms or mutations (compared to the known sequence of the vaccine strains). Such variants have been observed for oral polio vaccine (OPV), mumps virus, and VZVs but are not known to affect attenuation.

Advances in Monoclonal Antibody Isolation

The neutralizing determinants on vaccine Ags are *de facto* the epitopes recognized by human Abs that mediate antiviral function. The study of the molecular and structural basis for neutralization has been limited by the difficulty in isolating human mAbs. Recent breakthroughs in this field using enhanced EBV transformation with CpG,³⁴ human hybridoma formation,⁴⁶⁷ plasmablast sorting and cloning,⁴⁵⁶ single B-cell sorting and expansion,⁴⁴⁰ and other techniques have increased the numbers of human Abs for study by several orders of magnitude. Structural studies of complexes of human Abs with viral Ags have begun to yield fascinating insights into the features of protective Ab epitopes, which often are conformational, quaternary, and otherwise complex.²³⁷

Advances in Structural Biology

The ability to design optimal antigenic surfaces for induction of neutralizing Abs has long been a dream of vaccine scientists. The goal is to develop synthetic constructs that elicit Abs with predetermined structural specificity. In particular, induction of Abs against epitopes that are hidden in the native viral protein has been a challenge for vaccine design. Investigators working in the areas of structural biology and computational modeling

FIGURE 14.5. History of viral vaccines. Viral vaccines can be organized by the major technology that made their development feasible. Licensed viral vaccines are listed on the left axis in chronological order. They are color coded, indicating the major development era or technology with which they were associated. Significant advances since the initial age of empiricism have been coincident with the development of cell culture techniques and molecular biology. One can envision that advances in some of the technologies discussed in the text, such as structural biology, advances in sequencing, and gene expression vectors, may facilitate vaccine development for unmet and unanticipated future needs for prevention of viral diseases.

recently have made significant progress in this regard. Computationally designed epitope-scaffolds that are immunogenic have been developed for the HIV-1 gp41 epitopes of the broadly neutralizing mAbs 2F5³²⁶ and 4E10⁹³ and the RSV F motavizumab epitope.²⁷⁴ Structural information from HIV gp120 CD4 binding site epitope recognized by the neutralizing Ab b12 has been used to design gp120 reagents to select additional CD4 binding site Abs that have broad neutralizing activity against HIV.⁴⁷⁴ Fragments of influenza HA have been expressed to focus the immune response to conserved epitopes in the HA stem region.⁴¹ Computational and structural tools also can be used for design of viral inhibitors—for example, the design of proteins targeting the influenza HA stem that mimic the action of neutralizing Abs. It seems likely that computationally designed Ags will increasingly influence viral vaccine design.

LIVE VIRUS VACCINES

History of Methods for Isolating Attenuated Strains

Varying methods have been used to achieve attenuation for live virus vaccines. Type 2 poliovirus, strain 712, one of the three poliovirus vaccine strains in the live vaccine preparation, is a naturally occurring attenuated human poliovirus that was identified by its lack of virulence for the brain and spinal cord of monkeys.³⁸² Adenovirus vaccine strains (types 4 and 7) are wild-type human respiratory viruses used in the U.S. military that produced an asymptomatic infection following oral administration that was restricted in replication to the intestinal tract.⁶⁸ The remaining attenuated vaccine viruses were derived from wild-type human viruses by serial passage in cell cultures prepared from an unnatural host, leading to the emergence of mutants that were partially restricted in humans at the portal of entry and/or the target organ(s). In this manner, attenuated mutants of rubella virus and types 1 and 3 poliovirus were selected after passage in monkey kidney tissue culture. Vaccine strains of yellow fever virus (17D strain) and measles virus were generated by multiple passage in chick embryo cell culture, whereas mumps virus was attenuated by multiple passages in embryonated eggs.

A critical feature of most successful live vaccine development programs is the identification of preclinical laboratory predictors of attenuation. For the yellow fever virus and poliovirus vaccines, promising vaccine strains were identified by their attenuation for experimental animals. In monkeys, the 17D strain of yellow fever virus exhibited decreased tropism for the liver, suggesting that this mutant might be suitably attenuated for humans⁴²³—a hypothesis that was confirmed during subsequent clinical trials. Naturally occurring or tissue culture-passaged strains of poliovirus were evaluated for neurovirulence in monkeys by intraspinal inoculation, which was a central innovation that allowed Sabin to identify attenuated strains.^{381,382} This testing system was selected because several observations suggested that the spinal cord of monkeys was more permissive than that of humans to the neuronolytic effect of poliovirus.³⁸² Viruses that caused the least neurovirulence in monkeys were identified, and these strains then were cloned and recloned biologically by the plaque technique to yield progeny with the lowest possible level of monkey neurovirulence. These

candidate vaccine strains then were subjected to additional cycles of selection, which led to the identification of mutants that replicated with high efficiency in the intestinal tract without significant increase in neurovirulence for nonhuman primates. These viruses were evaluated in clinical trials and were shown to be satisfactorily attenuated and immunogenic.

Experimental animal systems were not available for evaluating virulence of the other vaccine viruses. Therefore, these viruses were tested for attenuation directly in humans. Initial candidate measles and rubella virus vaccines were insufficiently attenuated, although further passage of rubella virus in monkey kidney cell culture and selection of a cold-adapted, temperature-sensitive mutant of measles virus yielded satisfactory vaccine strains. Attenuation of mumps virus passaged in eggs also was determined in humans. Interestingly, the Jeryl Lynn strain of mumps virus vaccine developed by Maurice Hilleman as a clinical isolate from his daughter was found to be a mixture of two closely related strains of mumps virus.⁷ Several other vaccines have been found to be mixtures of virus strains, including the yellow fever virus vaccine and some vaccinia stocks used for smallpox vaccination.

Poliovirus and adenovirus vaccines are administered orally, whereas yellow fever, rubella, measles, and mumps virus vaccines are given parenterally. Each of the currently licensed live virus vaccines is directed against a virus that has a complex pathogenesis of infection in which virus is introduced by inoculation (yellow fever) or by implantation on a mucosal surface (measles, mumps, rubella, and poliovirus) with subsequent spread systemically to the target organ(s). The requirement of such viruses to pass through blood to reach the target organ of disease makes them generally susceptible to serum Abs. It is more difficult to protect against infection by viruses that cause disease at a mucosal portal of entry without the need for viremia.

Advantages of Live Virus Vaccines

The major advantage of live virus vaccines is the activation of all components of the immune system yielding both a balanced systemic and local immune response and a broad humoral and cell-mediated response. This type of comprehensive induction of immune effectors is particularly important for infections in which cell-mediated immunity plays an important role and for mucosal infections in which both local and systemic immunity are required for optimal resistance. As noted, mucosal infection with a live virus vaccine is much more effective in stimulating a local response in the unprimed host than inactivated virus vaccines administered parenterally.³⁰⁵ Live virus vaccines also can stimulate an immune response to each of the protective Ags of a virus, and this obviates the difficulties that arise from selective destruction of one of the protective Ags that may occur during the inactivation process and can lead to disease potentiation. This advantage is especially important for complex viruses encoding many protective Ags, because it is prohibitively difficult and expensive to immunize with multiple purified proteins or to construct multivalent vectors. Furthermore, immunity induced by live virus vaccines is generally more durable and more effective.²⁰⁴ There are practical advantages to many live virus vaccines, such as relatively low cost of production and ease of administration. Live viruses contribute to protection in populations because of the induction of herd immunity, sometimes facilitated by transmission of vaccine viruses from a

recipient to a contact. The effectiveness of live vaccines in settings of high transmission is illustrated by the use of adenovirus vaccines. Adenovirus vaccines have reduced military respiratory disease morbidity significantly over the past three decades. In 1995, however, the manufacturer of these vaccines ceased production owing to budgetary constraints. Major outbreaks of serious adenovirus infections occurred in military facilities as a consequence.

Disadvantages of Live Virus Vaccines

The major concerns with live virus vaccines are that they (a) can contain adventitious agents; (b) can cause illness directly; (c) can lose their attenuation during manufacture or during replication in vaccinees by reversion or by second-site compensatory mutations; (d) can spread to contacts; and (e) can lose infectivity during storage, transport, or use. The potential for contamination with live adventitious agents always exists as discussed previously. Sources include the original clinical sample from which the virus was isolated, cell culture substrates, laboratory reagents of animal origin (such as serum supplements and trypsin), and contamination from laboratory workers or environments. Cross-contamination of vaccine lots with other viruses in a laboratory facility is possible. Fortunately, contamination of clinical lots of vaccine with major human pathogenic adventitious agents has rarely been a problem in the modern era. Some of the early lots of live poliovirus vaccine were contaminated with live SV40, and the live yellow fever virus vaccine was initially contaminated with an avian leukosis virus. Follow-up of individuals who were given live vaccine contaminated with SV40 or avian leukosis virus has failed to identify any long-term adverse effect, including cancer, associated with exposure to these adventitious viruses.^{291,412,446}

Some live virus vaccines, such as the measles virus, rubella virus, and yellow fever virus vaccines, retain a low level of residual virulence. The reactions produced by these vaccines generally are minor and have not interfered with acceptance and widespread use of these products. A more serious problem is that of restoration of a varying degree of virulence during infection by vaccine virus. This occurs with the poliovirus vaccine at an extremely low frequency—that is, about one in 10^6 to 10^7 immunizations.³¹⁹ Most vaccine-associated cases of paralysis in vaccinees or their close contacts occur after the first dose and involve the type 3 vaccine strain.³¹⁹ A significant proportion of the paralytic illnesses associated with poliovirus vaccine occurs in individuals who are immunocompromised; however, this may not represent a manifestation of genetic alteration of vaccine virus.³¹⁹

The genetic basis for the very rare increase in virulence of the poliovirus vaccine strains during replication *in vivo* is relatively well understood. However, a paradox exists in that mutation toward a higher level of virulence for the CNS occurs rapidly and frequently during replication of poliovirus in the intestinal tract of vaccinees, although vaccine-associated paralytic disease is extremely rare. During manufacture of vaccine, the mutations that are associated with restoration of virulence can be detected at variable low frequency by sequence analysis, and neurovirulence of the final product can be held to a low level by rejecting vaccine lots that exceed the accepted standard for frequency of these mutations.⁷⁶ Genetic instability was also a problem with the 17D yellow fever virus vaccine during early field trials. Encephalitis was observed in 1% to 2% of young

vaccinees administered virus that had been passaged 20 times beyond the original seed lot.¹³⁷

The problem of genetic instability of live attenuated virus vaccines following replication *in vivo* is an even larger concern for viruses that can cause latent or persistent infection *in vivo* such as herpes viruses or lentiviruses (e.g., HIV). Despite this concern, successful vaccines have been developed for VZV—a herpesvirus that causes chickenpox and zoster—indicating that a successful live attenuated vaccine can be developed for a virus that causes a lifelong infection in humans. This vaccine was licensed first for prevention of childhood chickenpox and has recently been shown to significantly reduce the risk of VZV reactivation or shingles.³³³

Rubella virus can be recovered from the lymphocytes of immunologically normal individuals with arthritis up to 6 years after immunization or natural infection⁶⁹; however, the rubella virus vaccine does not appear to be associated with chronic arthritis.³⁶⁴ Interestingly, persistence of measles vaccine virus has not been detected, nor has the vaccine virus been implicated in subacute sclerosing panencephalitis.²⁸¹ Instead, widespread use of live measles vaccine has almost eradicated this rare but serious sequelae of persistent wild-type measles virus infection.

Several other concerns have been identified for live attenuated virus vaccines. First, there is a theoretical risk that infection of the fetus could occur following vaccination during the first trimester of pregnancy. For rubella vaccine, there is concern that vaccination might lead to development of the congenital rubella syndrome; however, the actual risk appears to be negligible.³³⁹ Second, naturally occurring wild-type viruses may interfere with infection by a live virus vaccine, resulting in a decrease in vaccine efficacy. Such interference has been observed primarily with live poliovirus vaccine strains and is caused by a wide variety of enteric viruses. This phenomenon has also been seen with experimental live attenuated alphavirus vaccines.²⁷⁰ To overcome this viral–viral interference, multiple doses of polyvalent live virus vaccines are required to assure a protective immune response to each component. Third, defective interfering particles have been identified in preparations of live virus vaccines,⁵⁵ and it is likely that they are present in all live virus vaccines to some degree. Fourth, live attenuated measles virus vaccine has been associated with a generalized immunosuppression that was observed to be directly correlated with the level of immune response to the vaccine.¹⁹⁹

Finally, it should be noted that stability is a serious practical problem with thermolabile vaccine viruses such as measles virus. The need for storage and transport of measles vaccine at low temperature (4°C) has limited its usefulness in some tropical areas where maintenance of a “cold chain” for transport and storage is difficult. Some simple solutions for stabilizing other live virus vaccines have been identified, such as lyophilization of vaccinia virus or using deuterium oxide for water in live poliovirus or influenza vaccine formulations,^{200,283} although additional work is needed.

Genetic Basis for Attenuation of Live Viruses

Mutants selected by passage in an unnatural host accumulate many mutations, often making it difficult to define in a precise manner the genetic basis for their attenuation. In some cases, the molecular basis of attenuation has been defined. The genetic basis of this neuroattenuation of each of the three poliovirus

vaccine strains has been partially defined.¹⁷⁰ Surprisingly, few mutations are involved. Analyses have identified attenuating nucleotide substitutions in 5' noncoding sequences and others attenuating in the 3' noncoding region or in the structural or nonstructural coding regions of type 1, type 2, or type 3 polioviruses.^{45,147,367} These mutations can now be monitored during manufacture and following replication *in vivo*. Vaccine lots with an increased frequency of reversion at some residues have been shown to exhibit increased neurovirulence, and such lots can be discarded as unacceptable for human use.⁷⁶ Thus, it is now possible to use molecular virological techniques to control the manufacture of vaccines by identifying the presence of the desired attenuating mutations as well as the absence, or low frequency, of unwanted reversions.⁷⁶

The Jennerian approach to the development of live attenuated viruses involves the use of a virus strain of mammalian or avian origin to immunize humans against a human virus that is related antigenically to the animal or avian strain. Mammalian and avian viruses that are well adapted to their natural host often do not replicate efficiently in humans and hence are attenuated. At present, we lack a complete understanding of the genetic basis for this form of host-range restriction. However, those mammalian or avian viral genes that have been identified as being responsible for host-range restriction in humans exhibit significant divergence of nucleotide sequence from that of the corresponding human viral genes. Quadrivalent and pentavalent rotavirus vaccine are examples of the Jennerian approach to vaccine development in which a nonhuman rotavirus strain, the rhesus rotavirus or bovine rotavirus, was found to be attenuated in humans. Because there was a need for a multivalent vaccine that would induce resistance to each of the major human rotavirus serotypes, the Jennerian approach was modified by constructing three reassortant viruses, each of which contained 10 rhesus rotavirus or bovine rotavirus genes plus a single human rotavirus gene encoding one of the major neutralization Ags of the targeted serotypes.

Conventional techniques for attenuation of viruses such as passage of virus at low temperature, mutagenesis followed by selection of mutants with the desired phenotype(s), or passage of virus in heterologous tissues continue to play a significant role in the development of live virus vaccines. These techniques have been used to generate candidate vaccine strains for CMV, ortho- and paramyxoviruses, alphaviruses, flaviviruses, hepatitis A virus, and arenaviruses. Selection for a combination of phenotypes (such as cold adapted and *ts*) is thought to be desirable because the different mutations can have synergistic effects on the stability of the attenuation phenotype *in vivo*.³⁰⁴ Viruses bearing stable, molecularly defined, identifiable attenuating mutations or attenuating gene constellations represent the vaccine strains of the future, because the genetic basis for attenuation will be known and can be monitored directly during all phases of vaccine development, manufacture, and utilization in humans.

The function of viral proteins can be altered by mis-sense mutations, insertions, or deletions. Classically, attenuated viruses were identified using biologic phenotypes: (a) *ts* mutants; (b) cold-passaged (*cp*) or cold-adapted (*ca*) mutants; (c) small plaque mutants; (d) protease activation (*pa*) mutants (also designated as cleavage mutants); and (e) mutants with altered interaction with host cell receptors. With modern molecular techniques, virulent viruses also can be attenuated

by a wide variety of creative approaches including gene deletion, shuffling of gene order, alteration of noncoding regulatory regions contain cis-acting signals required for efficient replication, the use of gene incompatibility in chimeric genomes, and the insertion of genes that encode proteins with known antiviral activities or with known immunoregulatory functions.

INACTIVATED VIRUS VACCINES

Inactivated virus vaccines are available in the United States for the prevention of disease caused by nine separate viral agents (see Table 14.1). The available vaccines are based on either whole inactivated virus or virus-like particles (VLPs) produced from purified protein. The viruses are grown in a variety of cell substrates, including eggs (influenza types A and B), a continuous monkey kidney cell line (poliovirus types 1, 2, and 3), human diploid fibroblasts (rabies, hepatitis A), or mouse brain (JEV vaccine). Virus is then inactivated with a chemical such as formalin or disrupted with a detergent (influenza). The level of efficacy of inactivated viral vaccines differs: Inactivated poliovirus vaccine is highly effective in preventing disease, whereas influenza virus vaccine is only partially protective.

Features of Inactivated Virus Vaccines

Inactivated virus vaccines offer the advantage of immunization with the entire antigenic content of the virus with little or no risk of infection. Only rarely do such vaccines contain a contaminating adventitious agent or residual infectious virus that has resisted inactivation. For example, paralytic disease was produced by some of the early lots of inactivated poliovirus vaccine that contained residual infectious virus.^{313,327} Contamination by an infectious adventitious agent was also detected retrospectively in some early lots of inactivated poliovirus. This was of some concern because the contaminating simian virus, SV40, was oncogenic in hamsters.¹⁹⁴ Fortunately, long-term follow-up of individuals who were inoculated with SV40-contaminated vaccine during early infancy failed to show evidence of a vaccine-induced oncogenic effect.⁴¹² Another incident occurred in a research setting where live vaccinia virus was found to be present in a preparation of inactivated vaccinia–HIV recombinant virus being evaluated as a therapeutic vaccine in HIV-infected subjects. Unfortunately, an immunodeficient recipient of this vaccine developed progressive vaccinia caused by residual live virus in the inoculum.⁴⁷⁰ Several inactivated whole virus vaccines have potentiated disease rather than prevented it.^{143,219} This finding was first observed with formalin-inactivated measles virus vaccine.¹⁴³ Initially, this vaccine prevented measles; however, after several years, vaccinees lost their resistance to infection. When subsequently infected with naturally circulating measles virus, the vaccinees developed an atypical illness with accentuated systemic symptoms and pneumonia.^{143,310} Retrospective analysis showed that formalin inactivation destroyed the ability of the measles fusion (F) protein to induce hemolysis-inhibiting Abs, although it did not destroy the ability of the H (HA or attachment) protein to induce neutralizing Abs.^{320,321} When the H-specific Ab had waned sufficiently to permit extensive infection with measles virus, an altered and sometimes more severe disease was seen at the sites of measles virus replication.⁵³ This atypical disease is believed to be mediated in part by an altered cell-mediated immune response in which Th2 cells³⁵⁶ or

a delayed-type hypersensitivity reaction²⁴⁶ were induced preferentially, leading to heightened disease manifestations at the sites of viral replication. Immune complex deposition also plays a role in the pathogenesis of atypical measles.³⁵⁷

Potential of disease also was observed after parenteral administration of an experimental formalin-inactivated respiratory syncytial virus (FI-RSV) vaccine.²¹⁹ In clinical trials conducted in the mid-1960s, an FI-RSV vaccine induced a measurable serum-neutralizing Ab response but did not protect the youngest vaccinees. Unexpectedly, on subsequent natural infection with RSV, the FI-RSV vaccinees developed severe RSV lower respiratory tract disease significantly more often than did infants and young children who had received an inactivated parainfluenza virus vaccine.²¹⁹ Speculation on the mechanism of disease potentiation by the inactivated RSV vaccine has centered on several possible aberrations of the immune response to vaccine that involve an imbalance between or within various compartments of the immune system. Most likely, the protective antigenic sites on the F protein were altered by fixation, and the altered Ag induced an aberrant T-cell and cytokine response leading to enhanced disease as recently reviewed.¹⁶⁵ The major lesson learned from the FI-RSV vaccine-enhanced illness is that the chemical treatment and physical purification procedures used for the preparation of each new inactivated vaccine should be evaluated not only for their effect on the magnitude of immune responses but also on the functional characteristics of the response. Typically, the Ab induced should have neutralizing activity, and the T-cell responses should mediate efficient virus clearance.

Potential of disease by an inactivated virus vaccine is not limited to vaccines containing measles virus or RSV and has occurred with both human and veterinary vaccines. For example, administration of an inactivated caprine lentivirus vaccine has also been associated with an accelerated, more severe disease in animals subsequently challenged with virus.²⁷³ Vaccine-enhanced pathology is also not limited to inactivated virus vaccines. Immunization with a subunit vaccine of another lentivirus—equine infectious anemia virus (EIAV)—enhanced disease caused by subsequent challenge with a heterologous EIAV strain.²⁰¹ A similar phenomenon occurred during the development of a vaccine for feline infectious peritonitis virus (FIPV). FIPV is a CoV that developed more notoriety after the emergence of the severe acute respiratory syndrome (SARS) CoV in 2003. Attempts to develop a vaccine against FIPV have been largely unsuccessful and associated with a vaccine-enhanced illness. A major problem is that Abs are not protective even when given passively for prophylaxis, and they can facilitate virus entry through Fc receptors. Whole virus,³⁴⁵ recombinant vaccinia expressing the major surface S (spike) glycoprotein,⁴³⁷ or DNA immunization with IL-12¹⁵⁰ all have led to enhanced disease syndromes. Immunization of ferrets with a recombinant modified vaccinia virus Ankara (MVA) expressing the S glycoprotein has also caused an enhanced disease with hepatitis after SARS CoV immunization. Although the immunological mechanisms responsible for these examples of enhanced disease have not been identified, there are two common features present in these settings to consider. First, there was induction of a memory T-cell response in the absence of prechallenge Ab that could effectively neutralize virus. This is analogous to the conditions associated with measles and RSV vaccine-enhanced disease. Second, these are viruses that have

tropism for Fc receptor bearing cells. The presence of binding Ab that does not effectively neutralize virus could thereby facilitate entry and amplify viral replication. Vaccine studies with DNA or recombinant vectors, subunit proteins, or inactivated virus alone or in combination that have induced effective neutralizing Ab responses to the SARS CoV in animal models have not been associated with enhanced illness postchallenge.

Another disadvantage of inactivated virus particle vaccines is that they typically have to be given parenterally because without replication or gene expression, it is difficult for mucosally delivered Ag to elicit a significant inductive event. Parenteral induction of systemic immunity may not fully protect against viruses that infect and cause disease primarily at mucosal surfaces if the gradient of Ab between serum and mucosa is too large or the kinetics of viral entry are too rapid. Therefore, resistance to viral challenge in the upper respiratory tract or in the intestines may be less robust than that conferred by local immunization or infection. This may be the reason inactivated influenza vaccines are only partially protective, and why the inactivated polio vaccine (IPV) can prevent paralytic polio but cannot prevent poliovirus infection and intestinal carriage. There are clear exceptions to this principle, which are best exemplified by the success of parenterally administered HPV vaccine. Although HPV is a purely mucosal pathogen, it has recently been shown that entry into basal epithelial cells is a two-step process that may take several hours.²²² Virus neutralization can be accomplished with much less Ab when given longer access to the viral antigenic sites.

Inactivated virus vaccines are clearly at a disadvantage compared to either live attenuated virus vaccines or vector-based gene delivery with respect to induction of a CTL response. CD8 CTL responses require Ags to be processed through the proteasome so that peptides can be transported into the endoplasmic reticulum and associate with MHC class I molecules. This is best achieved when proteins are synthesized in the host cell cytoplasm and is rarely achieved in primates when Ags enter the APC through the endocytic pathway. For example, inactivated influenza virus is considerably less effective than virus infection in stimulating a primary CTL response in mice. However, inactivated influenza A virus or purified surface glycoproteins derived from it can sometimes stimulate a secondary CTL response in sensitized mice or humans.^{5,122} There are new adjuvants and delivery vehicles that have the capacity for moving purified proteins into the MHC class I presentation pathway, and these may be considerations for future vaccine development.

The Guillain-Barré syndrome was associated with widespread use of inactivated influenza A H1N1 (swine) virus vaccine during 1976 and 1977,²⁴⁰ indicating that unanticipated, delayed, or untoward side effects can be induced by inactivated virus vaccines. This syndrome has been associated only rarely with subsequent influenza virus vaccines and was not reported at all following the rapid introduction of vaccines against the 2009 H1N1 pandemic strain, even though these products were prepared in the same manner as the 1976 vaccine.²⁴⁰ The basis for this idiosyncratic syndrome associated with the 1976 influenza vaccine is still not defined.

Future Considerations for Inactivated Virus Vaccine Development

Formaldehyde, heat, and oxidation have been shown to produce reactive carbonyl groups on protein Ags that promote

CD4 T-cell responses with Th2 differentiation.²⁸⁵ Chemical inactivation of poliovirus during vaccine manufacturing can result in modification of a major neutralization epitope. Therefore, inactivating infectivity of nonenveloped and enveloped viruses can adversely affect the antigenicity of the vaccine.¹³⁰ It has also been recognized that antigenic changes can occur during selection and amplification of influenza viruses in the allantoic cavity of embryonated eggs—the substrate used to produce virus for the inactivated vaccine.³⁷⁰ The genetic basis for these mutations involves host cell selection of mutants that replicate more efficiently in eggs. These variants acquire a mutation in or near the receptor binding pocket of the HA that increases their efficiency of replication in eggs but also alters antigenicity and immunogenicity. Nevertheless, influenza viruses that are used to prepare inactivated vaccine for humans are grown in eggs, and such vaccines have been repeatedly shown to be protective. Although this would not be a problem for influenza vaccines produced in mammalian cell culture, vaccine Ags may be modified or processed in ways that compromise antigenicity even in mammalian cell substrates. For example, poliovirus grown in tissue culture contains an uncleaved outer capsid protein, VP1, which is usually cleaved in a natural infection by intestinal proteases. Although tissue culture–grown poliovirus has limited ability to induce Abs that neutralize viruses containing a cleaved VP1,³⁷¹ both cleaved and uncleaved VP1 can induce protection from replication of subsequently administered live attenuated poliovirus vaccine.³⁵⁰ Nevertheless, careful assessment of the substrate-dependent antigenicity and consequences of inactivation is warranted in the development of inactivated virus vaccines.

VIRUS-LIKE PARTICLE VACCINES

There are licensed VLP vaccines for two viral pathogens (HBV and HPV). The VLPs are produced as self-assembling capsid proteins in yeast or insect cells. For the purposes of this section, we will define VLP as self-assembling viral proteins that can mimic the particle structure of virions and present the quaternary structures of oligomeric viral surface proteins but do not package the virus genome. There are other self-assembling nonviral proteins that can be used to display vaccine Ags that are mentioned with nanoparticles in the Delivery Vehicles section.

The initial version of the HBV vaccine was based on surface Ag purified from the blood of persons persistently infected with HBV. The Australia Ag was associated with the disease caused by HBV, and later the Dane particle was found to represent the Australia Ag. Interestingly, electron microscopy revealed not only the Dane particle, which is a 42-nm structure representing the complete infectious virion, but also smaller particles and filaments. The 22-nm particle was found to be comprised of just HBsAg and is noninfectious because it does not contain nucleic acid. This small particle, purified from human plasma, was the first licensed HBV vaccine. An effective second-generation HBsAg vaccine was developed using a recombinant plasmid to express the gene for HBsAg in yeast. Yeast-produced HBsAg self-assembles into uniform 22-nm particles. Although the 22-nm noninfectious particle is smaller in size and technically a defective genomeless subvirion particle, it is considered a VLP because it is made of

the same capsid protein (HBsAg) as the full particle. Licensed HBV VLPs are formulated with alum and are now part of the routine pediatric vaccine schedule. This vaccine often is protective against HBV infection and hepatitis even in the absence of detectable Ab response. Immunization against HBV also significantly reduces the frequency of hepatoma and is regarded as the first anticancer vaccine.⁶⁷ The immunogenicity of HBV VLP in patients with renal failure, HIV-1 infection, or other immunocompromising conditions is diminished. New adjuvant approaches such as formulation with CpG (TLR-9 agonist), monophosphoryl lipid A (MPL)+alum, or MPL+QS21 are being explored to improve vaccine-induced immunity in those settings.^{32,33,91} HBV VLPs are now produced for human use in nine countries using yeast, bacteria, or mammalian cells for manufacturing, and other substrates including transgenic plants are being explored.³⁷⁵

HPV particles were first identified by electron microscopy in 1949. In 1983, the association between HPV infection and cervical dysplasia and malignancy was proven.¹¹⁷ In 1991, it was shown that VLPs lacking genomes could be produced by expression of the L1 and L2⁴⁷³ or just the L1²²⁴ capsid proteins of papillomaviruses. L1 self-assembles into pentamers, and each VLP is comprised of 72 pentameric capsomeres. If present, one L2 protein is associated with the center of each L1 pentamer on the inner surface of the capsid. These key discoveries led to the development of candidate VLP vaccines. Importantly, the end points for the efficacy trial were chosen carefully. Although prevention of cervical carcinoma was the goal, this target was not an acceptable end point because ablative treatment would be performed if premalignant lesions were detected. Therefore, cervical intraepithelial neoplasia grade 2 or higher was used as the end point for vaccine efficacy trials as a surrogate for cervical carcinoma. Prevention of persistent serotype-specific HPV infection was also a primary end point. Yeast-produced HPV 16 VLP formulated in alum and delivered parenterally was 100% effective in preventing cervical intraepithelial neoplasia.²³² A three-dose regimen of a tetravalent L1-based VLP vaccine based on HPV 16 and 18 (most common causes of cervical intraepithelial neoplasia) and HPV 6 and 11 (most common causes of anogenital warts) is also highly effective.⁴³⁹ Subsequent studies have shown that HPV VLP immunization can prevent HPV-induced cervical lesions in women⁴ and anogenital lesions in both women and men.^{146,149} Three doses containing 30 µg of each of the four VLPs formulated with aluminum hydroxyphosphate sulfate (Gardasil) or 20 µg of each of two VLPs formulated with a mixture of aluminum hydroxide and 3-deacylated MPL (AS04) (Cervarix) are sufficient to achieve protective immunity that is durable for more than 5 years.³⁷⁴ The protection has been correlated with type-specific neutralizing Ab. A nonavalent VLP vaccine including serotypes 6, 11, 16, 18, 31, 33, 45, 52, and 58 is being evaluated in efficacy trials in an attempt to extend the coverage against cervical neoplasia from 70% to more than 90%.

Advantages of Virus-Like Particle Vaccines

Capsid proteins from many nonenveloped viruses and the nucleocapsid or matrix proteins together with surface proteins from some enveloped viruses can self-assemble into VLPs and provide a platform technology that may be applicable as vaccines for multiple virus families. VLPs offer several advantages as immunogens. First, the viral nucleic acid is not present in

VLPs, thus there is no concern that viral oncogenes or other pathogenic features of the live virus are present. Second, VLPs present conformational epitopes to the immune system in the same way as native infectious particles so that neutralizing Abs and other protective immune responses are induced efficiently. Some of these epitopes are formed by the juxtaposition of parts of two different capsid proteins. Third, many of the non-enveloped viruses from which immunogenic VLPs have been developed replicate poorly or not at all in tissue culture (e.g., B19 parvovirus, papillomaviruses, and hepatitis E virus), thus precluding the use of purified virus as immunogen. Fourth, because VLPs are noninfectious, chemical inactivation is not required. For this reason, VLPs might prove to be better immunogens than formalin-inactivated whole virus vaccines because the deleterious effects of formalin on structure and immunogenicity can be avoided. Fifth, the immune system responds better to a viral Ag presented as an assembled multimeric particle rather than as an individual monomeric protein. Sixth, the stability of VLPs from nonenveloped viruses may simplify vaccine storage and distribution and also make successful oral delivery feasible in some cases.³¹⁸

Disadvantages of Virus-Like Particle Vaccines

The major disadvantage of VLP vaccines is related to the cost and complexity of manufacture, although costs should become lower with advances and expansion of the options for cell substrates. The biological disadvantage of VLPs compared to replication-competent viruses or vectors is that there is not ongoing production of Ag following vaccination. However, these particles tend to be highly antigenic and stable, and immunogenicity can be enhanced with adjuvants.

Future Considerations for Virus-Like Particle Vaccine Development

VLPs have been engineered successfully for viruses belonging to a wide range of virus families, including both nonenveloped and enveloped viruses. Because of the advantages listed previously and track record of success, they should be considered as a vaccine platform technology for other virus families when possible.

Nonenveloped Virus-Like Particles

The first characterization of synthetic VLPs followed the observation that picornavirus capsid proteins could self-assemble during the *in vitro* translation of viral RNA to yield 75S to 85S particles.³³⁵ Later studies indicated that VLPs could form *in vitro* following translation of picornavirus viral RNA lacking most of the 5' noncoding region.⁸⁰ Next, it was observed that expression of the open reading frames of capsid proteins of non-enveloped viruses by a baculovirus or vaccinia vector in appropriate eukaryotic cells resulted in generation of VLPs.^{81,224,473} For picornaviruses, particle assembly requires expression of the entire open reading frame to permit the proteolytic processing of the structural proteins by nonstructural viral-encoded proteases. There are current vaccine development approaches being used for enterovirus 71 that involve VLP technology.⁷⁸

Human parvovirus B19 causes erythema infectiosum, acute and chronic red cell aplasia, and other illnesses. A vaccine candidate consisting of the human parvovirus B19 VP1 and VP2 capsid proteins that form VLPs is being developed.²² Immunization of humans with this vaccine induces neutralizing

Abs that achieve levels equivalent in magnitude and neutralizing activity to those seen following natural infection.⁴⁴ Antigenic VLPs can be readily produced for other human (bocavirus)⁶⁶ and veterinary parvoviruses,³⁷³ suggesting that VLP-based vaccines may be an appropriate approach for pathogens for this viral family.

Norovirus, the prototypic member of the calicivirus family, also may be a good candidate target for a VLP vaccine. The virus is a 28- to 37-nm nonenveloped particle that is formed by a single major capsid protein (VP1). VP1 is a protein with two domains connected by a short linker. The P domain forms the outer surface of the particle, and the S domain forms an inner shell. The P portion of VP1 can self-assemble 24 protomers to form a 20-nm particle that is immunogenic.⁴¹⁷

Enveloped Virus-Like Particles

Expression of the nucleoprotein or matrix proteins of some enveloped viruses has also resulted in the production of VLP or virus pseudoparticles. This finding was noted first for the Gag protein of HIV when it was expressed in recombinant vaccinia-infected cells.^{178,196} Production of purified HIV pseudovirions is being developed as a vaccine strategy,¹²⁷ and the construction of vectors that are competent to produce pseudovirions *in vivo* may improve immunogenicity beyond that of the simple expression of the isolated gene products.^{72,182} VLPs have now been produced for several respiratory viral pathogens. Expression of M1, M2, NA, and HA can form influenza VLPs²⁴¹; however, HA is sufficient in the presence of NA.⁷¹ These are potent immunogens that can be constructed to express Ags that can confer broad cross-reactivity⁴⁰⁶ or TLR agonists that can provide adjuvant properties.⁴⁴¹ SARS CoV pseudoparticles are formed by transfection of 293 cells with the M (membrane) and N (nucleocapsid) genes.¹⁹⁷ The M protein of Newcastle disease virus (NDV) is sufficient to produce VLPs³³⁷ that can support the incorporation and display of RSV F and G and is immunogenic and protective in animal models.²⁷² The NDV VLPs appear to be a stable platform for presentation of viral glycoproteins from other viruses as well.²⁹⁰ Alphaviruses and flaviviruses are also potential viral targets for VLP vaccines. For example, West Nile virus pseudoparticles are formed by co-expression of prM and E.¹⁸⁴ Recently, chikungunya virus VLPs were produced that protected rhesus macaques from lethal challenge.⁸

Novel chimeric particles in which viral Ags are built onto the hepatitis B core VLP⁴³ are immunogenic in mice. Relatively large structures can be mounted on the recombinant VLPs if inserted covalently into the outer loops or attached through chemical conjugation in the right place and orientation to allow access to the vaccine Ag being displayed. Other chimeric VLPs can be constructed by inserting candidate vaccine Ags into the variable loops that face outward, including norovirus P particles,⁴¹⁸ Chikungunya,⁸ or others, and could be selected based on the desired particle size and Ag valency (Fig. 14.6).

OTHER VACCINE APPROACHES

Molecular biology has been an important stimulus for new approaches to make live attenuated virus vaccines. As well, it has provided avenues for production of subunit vaccines and gene delivery vehicles that express viral Ags (e-Fig. 14.9). MAB

FIGURE 14.6. Variations on VLP size and structure. VLPs assume a wide range of sizes and are shown here as images derived from cryo-electron microscopy. Hepatitis B (HBV),¹¹³ hepatitis E (HEV),⁴⁶³ bovine papillomavirus (PV) representative of other papillomaviruses,⁴⁵⁵ and chikungunya (CHIKV)⁹ are shown by order of increasing size. VLP, virus-like particle.

and recombinant DNA technology are now used routinely to produce large quantities of purified viral Ags for use in immunoprophylaxis. MAb immunoaffinity chromatography or lectin chromatography facilitates purification of viral Ags from infected cells, whereas recombinant DNA technology makes it possible to express viral proteins in eukaryotic cells of yeast, insect, or mammalian origin. The use of these techniques has yielded candidate vaccines encompassing a large array of viral proteins that are capable of inducing protective Abs in experimental animals. Immunization by gene delivery is emerging as an important way to mimic certain aspects of live virus infection and can be accomplished by a growing list of delivery methods.

Vaccination With Proteins or Peptides

There are several theoretical advantages to immunizing with selected viral Ags instead of using whole virus particles. Production of recombinant viral proteins or synthetic peptides diminishes the risk of contamination by unrecognized pathogens. In addition, the preparation of vaccines free of nucleic acid eliminates theoretical concerns about recombination or integration of viral nucleic acid. Immunizing with individual Ags or epitopes from the virus might also reduce antigenic competition and focus the response on the most relevant protective antigenic sites.

Production of Viral Proteins in Eukaryotic Cells

Before expression of viral proteins in eukaryotic cells can be used as a method for vaccine production, several obstacles must be overcome. First, it is essential to identify the correct immunogen. Second, it is necessary to produce protein in a highly efficient manner to make this approach economically feasible. Mechanisms to enhance expression of viral proteins that have been pursued focus primarily on identification of strong promoters of gene expression and development of techniques for efficient gene amplification. Third, viral proteins must be separated effectively from host cell protein, DNA, and endogenous adventitious agents. Lastly, the proteins must be produced with the desired structure and activity. This latter requirement is of special concern, as immortalized mammalian cell lines are ideal for producing viral proteins because posttranslational modifications are more likely to be authentic than when these proteins are produced from prokaryotic hosts. Host cell DNA must be greatly reduced in the final vaccine (FDA guidance is <10 ng/dose) to reduce the theoretical potential for oncogenic events. Additionally, removal and inactivation of endogenous

viruses must be performed for products made from continuous rodent and other mammalian cell lines. Recombinant DNA techniques to promote secretion of viral glycoproteins into the medium have been developed to facilitate effective separation of viral proteins from host cell proteins. Fourth, the procedures used to produce and purify viral protein must be gentle enough to maintain the protein in its native state, thereby preserving conformationally dependent neutralization epitopes needed to induce protective Abs. Finally, because purified monomeric proteins are typically weak immunogens, they need to be formulated with adjuvants or produced as oligomers or particles to enhance their immunogenicity. The following discussion of these approaches is not intended to be exhaustive in scope but illustrative of current strategies in use or in development.

Recombinant DNA techniques are commonly used to express viral proteins in yeast, insect, or mammalian cells. The usefulness of yeast expression has been described previously for the production of the HBV vaccine and is also used to produce HPV VLPs.²⁵⁴ Some viral proteins such as the rabies G glycoprotein are more difficult to produce in yeast.³⁸⁴

A major advance in viral Ag production has been the development of baculovirus vectors to express foreign genes to high levels in insect cells under control of a strong baculovirus promoter, such as the polyhedrin promoter.²⁵⁷ Protein can be produced in large quantity (1 mg/10⁶ cells) using this system. Viral glycoproteins also can be produced in this system. For example, baculovirus-produced influenza HAs can be produced efficiently and have equivalent or superior immunogenicity to the traditional trivalent split product in adults²⁷ even though immunogenicity is significantly reduced in more immunologically naive children.²²³ The baculovirus system also can be used to express more complicated viral immunogens that require polyprotein processing to generate native immunogenic surface proteins. An example of this is expression of the entire structural protein region (C-E3-E2-6K-E1) of an alphavirus to generate authentic, processed viral proteins capable of inducing an efficient neutralizing Ab response in experimental animals.¹⁹³

Mammalian cells also have been used for the production of viral proteins that can be incorporated in a subunit vaccine. Mammalian cell cultures represent an optimal system for the production of viral proteins because protein folding, transport, and processing closely approximate those that occur in the infected host. Initial approaches were to purify viral proteins from infected cells or from cells transduced with a recombinant virus expression system engineered for high level of expression

of the foreign viral Ag^{140,141} or by transient transfection with DNA. More recently, cell lines have been developed that can stably produce recombinant proteins or Abs, can be modified for large-scale production, and have achieved regulatory approval for clinical products.

Chinese hamster ovary (CHO) cells have long been a preferred cell line for the production of protein-based therapeutics.⁴³¹ These cells have been used to produce viral glycoproteins from HIV and HSV that have been advanced to efficacy trials^{135,366,409} and can be modified to improve the manufacturing efficiency and capacity even further. Immortalized human cell lines derived from healthy human embryonic material have also emerged as producer cell lines for protein production such as 293 and PER.C6. Both lines have been used extensively to produce gene delivery vectors, have fully documented passage histories, and have had no adventitious agents or oncogenic or teratogenic potential identified to date. PER.C6 was derived from embryonic retina cells and immortalized with the adenovirus *E1* gene. The 293-ORF6 cell line has a similar development history and contains the adenovirus open reading frame 6 from *E4* as well as the *E1* gene.⁵⁴ These fully human cell lines may provide advantages for producing virus glycoproteins that authentically replicate the structures present in human infection, can be adapted to different growth conditions, and can stably produce high levels of recombinant protein without gene amplification.²⁰⁸ In general, identifying immortalized human cell line platforms for the production of proteins, VLPs, whole virus, or vaccine vectors will be preferable to using primary cell lines that have to be revalidated repeatedly or using less efficient production methods that require transient infection or transfection.

Production of Viral Proteins in Prokaryotic Cells

Production of immunogenic viral proteins in prokaryotic cells is difficult and requires extensive re-engineering of the gene to achieve immunogenic structures because of differences in protein processing and microenvironment. However, there have been some notable successes, especially in the production of VLPs. In particular, a portion of the structural protein from hepatitis E ORF2 produced in *Escherichia coli* self-assembles into particles and was shown to be efficacious in a 100,000-person study.⁴⁷⁵ HPV VLPs have also been produced in bacteria, although clinical trials have not yet been reported.^{249,311}

Production of Viral Proteins in Plant Cells

Plants have been modified genetically to express virus proteins^{63,415} and VLPs,⁹⁹ some of which have advanced to clinical trials. Plants can be engineered with selected mammalian glycosidases to provide more authentic posttranslational modifications.⁴¹¹ The major advantage of this approach is the potential for inexpensive and widely distributed manufacturing capacity.

Protein Purification

Immunoaffinity chromatography, lectin chromatography, and physical separation techniques have been used to purify a variety of viral glycoproteins that have induced partial to complete resistance in animals. When directly compared in animals, resistance induced by immunization is greatest when the purified viral glycoprotein is in its native conformation.⁴³³ In the case of RSV and EBV, purified glycoprotein vaccines induced Abs that were able to bind to glycoprotein in enzyme-

linked immunosorbent assays (ELISAs); however, these Abs had a very low level of neutralizing activity.^{302,452} In contrast to purified protein immunogens, RSV glycoproteins expressed by a vaccinia virus RSV F or G recombinant induced a titer of neutralizing Abs comparable to that developed by animals infected with the virus.⁸⁸ Observations of this type underscore the potential importance of quaternary structures and presentation of proteins in the context of membranes and organized on particles to achieve functional Ab responses.

Synthetic Peptides as Immunogens

During the early 1970s, the use of synthetic peptides as immunogens was studied using a synthetic icosapeptide representing the immunodominant domain of the outer coat protein of bacteriophage MS-2.²³⁹ This peptide, conjugated to a carrier and emulsified in adjuvant, induced Abs in rabbits that neutralized the infectivity of the bacteriophage when goat antirabbit Ig Abs were added to the mixture. Although synthetic peptides were shown subsequently to induce neutralizing Abs that did not depend on the aggregating effect of anti-Ig Abs and to stimulate immunity to certain animal viruses *in vivo*,³⁸ the immunity induced was less than that achieved when full-length protein, inactivated whole virus, or live virus was used as immunogen. The decreased immunogenicity of synthetic peptides is a consequence of their failure to mimic the conformational epitopes of viral surface proteins. Strategies to augment the immunogenicity of synthetic peptides, such as (a) inclusion of both B-cell and CD4 T-cell epitopes in the peptide, (b) synthesis of oligomeric peptide structures by using polylysine scaffolding,³¹² (c) presentation of peptide in a noninfectious viral particle, (d) expression of peptide by infectious virus, or (e) scaffolding of peptide epitopes with constrained conformational structure have not overcome the inherent deficiencies of this approach. Neutralizing epitopes from the membrane proximal region of HIV gp41 and the Synagis epitope from RSV were designed on protein scaffolds to mimic the structure and display the identical contact residues defined by the original peptide-Ab crystal structures. Although these novel Ags were immunogenic and induced Abs that bound HIV gp41 and RSV F, vaccinee sera did not have neutralizing activity.^{274,326} Using a much longer peptide may sometimes retain sufficient structural integrity to induce protective Ab responses. For example, a 100-aa peptide from the central region of RSV G can elicit neutralizing Ab to a central conserved region of the protein.³⁵⁸ Also, a 56-aa peptide from the stem region of the influenza HA can induce Abs to a conserved epitope that has some cross-neutralizing activity.⁴⁴⁴

The fact that CD8 T-cell epitopes are short peptides of 8 to 10 amino acids in length presented in the context of the MHC class I heterodimer suggested that it might be possible to produce peptide vaccines to induce CTL-mediated immunity.¹²⁰ CTL induction by peptide vaccines has been achieved in several experimental systems. For example, a peptide in adjuvant induced CTLs and protected mice against Sendai virus infection.²¹⁵ Thus far, peptide vaccines have not achieved significant immunogenicity when used in immunologically naive humans unless formulated in preparations with strong adjuvants that are associated with unacceptable reactogenicity. Also, the reductionist approach to vaccine Ags has not been successful when tested in humans. In general, it is better to use a larger antigenic content in vaccines for viruses so that the individual hosts can

select the most relevant and effective epitopes for themselves. This principle is also consistent with the concept that vaccination has its largest impact on public health at the population level. Developing tailored, personalized vaccination approaches may be in the distant future for preventive antiviral vaccines, and this type of approach is being explored for therapeutic vaccines against neoplasms and some chronic virus infections. Indeed, immunization with mixtures of long peptides derived from HPV E6 and E7 oncoproteins formulated in incomplete Freund's adjuvant (IFA) has led to remission of HPV16-induced vulvar intraepithelial neoplasia.²¹⁷

Vaccination by Gene Delivery

The age of molecular biology has made it possible to build expression vectors that can serve as a vehicle for gene delivery of vaccine Ags. The development of this technology is attractive because it combines the immunogenicity advantages of live vaccines and the safety advantages of nonliving vaccines. Genes can be modified to be nonfunctional and harmless to the host, improve expression, and yet retain the antigenicity of the expressed protein. Using the host cell for transient protein production provides the opportunity for expression of more native structures than are possible with *in vitro* protein production including glycosylation patterns that may influence antigenicity. Genes can be produced synthetically so that no component of the original virus pathogen is needed in the manufacturing process to avoid the potential complications of infection with live viruses or adventitious agents. Selected immunogenic components of the pathogens can be expressed and combined with molecular adjuvants that enhance and guide the composition of immune responses. In addition, the mechanisms that viruses use to evade or alter immune responses can be removed, or genes can be modified (e.g., by adding ubiquitination sites) to improve processing and Ag presentation.⁴⁰⁴ Therefore, it may be possible to improve on the immunity afforded by natural infection by using vector-based expression of viral Ags. New delivery approaches, including vector technology, provide the opportunity to combine Ags from multiple strains or different pathogens to potentially allow broadening of vaccine-induced immunity while simplifying vaccination regimens. They can be categorized by their functional properties (e-Fig. 14.10) and other features that may influence vaccine strategies for a particular virus (e-Table 14.2).

DNA Vaccines

The concept of using bacteria-derived plasmid DNA to deliver vaccine Ags has many attractive features, including ease and flexibility of construction, scalable manufacturing capacity, stability, production of vaccine Ag in host cells, transient expression, no induction of antivector immunity, induction of a balanced CD4 and CD8 T-cell response in addition to an Ab response, and minimal local or systemic reactogenicity.²⁴²

It was originally found to be possible to express transgenes by direct intramuscular or intradermal inoculation of plasmid DNA in the early 1990s.^{419,454} The feasibility of immunization with DNA was demonstrated by the induction of Abs against human growth hormone in mice immunized with a plasmid encoding this foreign protein.⁴¹⁹ The first demonstration of DNA vaccine protection against a virus was in mice challenged with influenza.²⁸⁸ Subsequently, immunization with DNA that encoded viral Ags, including Ags that can form VLPs, from

a wide range of viruses has induced functional (i.e., neutralizing or syncytium-inhibiting) Abs and/or resistance to virus infection.¹¹⁰ Gene-based immunization promotes host cell synthesis and expression of the vaccine Ag and physiological posttranslational processing and folding in the cell cytoplasm. For these reasons, DNA vaccination can elicit both CD4 and CD8 T-lymphocyte responses with a variety of immunogens in animal models.

Immunization with DNA has several advantages over immunization with purified viral Ags. The most important advantage is that vaccine Ags such as viral glycoproteins can be expressed on the surface of transfected cells and are presented to the immune system in a native state. During the processes of purification of viral proteins, purification and assembly of VLPs, or inactivation of viruses with chemicals, epitopes on viral proteins can be altered that compromise immunogenicity. DNA immunization, which circumvents these problems, more closely resembles immunization with a live virus vaccine than with an inactivated viral Ag. Viral Ags encoded by DNA, whether entire proteins or minimal CTL epitopes, are presented efficiently in the context of MHC class I molecules and are able to induce CD4 T cells and CTLs.^{65,243,264,468} In this way, it is possible to induce a balanced immune response more similar to immunity induced by natural infection than to immunity induced by administration of preformed viral Ags. A second advantage of immunization with DNA is its ability to transfect cells without interference by antiviral or antivector Abs. Live attenuated vaccine virus, such as that present in the measles virus vaccine, is effectively rendered noninfectious by Abs. Likewise, Abs to gene-delivery vectors, such as adenovirus serotype 5 (Ad5), can diminish the immunogenicity of this approach, whereas DNA immunization is not affected by pre-existing Abs. Finally, it has been observed that the foreign Ag can be expressed *in vivo* for several months following DNA immunization.⁴⁶⁵ Protein expression can also be optimized by modifying the promoter elements (e.g., adding the translation enhancer element from the human T-lymphotropic virus type 1 [HTLV-1] LTR).^{26,243} It is thought that the major factor limiting the immunogenicity of DNA vaccines is inefficient transfection of cells. This is partially improved by using delivery devices such as Biojector, and new approaches utilizing electroporation offer the potential for improved potency of DNA vaccines.³⁸⁸

The safety profile of DNA vaccines in clinical trials has been excellent to date, without evidence of integration of the vaccine DNA into the human genome or induction of autoimmune reactions, which were some of the early theoretical concerns. Initially, DNA immunization showed limited immunogenicity in humans, despite many examples of vaccine-induced protection in mice and nonhuman primates.¹¹⁰ The first DNA vaccine demonstrated to be immunogenic in Ag-naïve humans expressed the circumsporozoite Ag from *Plasmodium falciparum* and was shown to induce CD8 CTL responses detected by *in vitro* expansion of effectors.⁴⁴³ Another report described a DNA plasmid expressing the HBsAg that induced Ab as well as vaccine-specific T-cell responses in Ag-naïve humans.³⁷⁸ Through improvements in promoter design, manufacturing process, and delivery, DNA immunization in humans is now showing promise as a platform for inducing significant neutralizing Ab^{243,264} and T-cell responses.¹⁶³

Replication-Competent Vectors

The molecular technologies that have made gene delivery possible in general have been applied to the development of stable attenuated virus vaccines, some of which have been used to construct viable recombinants that express the surface proteins of other viruses, thus blurring the distinction between live attenuated viruses and vaccine vectors. Chimeric or live recombinant virus vectors can be designed to deliver the foreign gene from a virulent pathogen in the context of a nonpathogenic expression system, thereby improving safety. The vector design can also take into account manufacturing issues to improve overall production efficiency. The use of a viral vector for immunization has the advantage that the foreign viral Ags are expressed naturally in the context of an infected cell, thereby inducing cellular and humoral immune responses. Vector selection and design can focus vaccine Ag expression to a particular target cell or immunological compartment to tailor the organization of an immune response to a particular pathogen. Delivering the vaccine Ag in a complex structure has the benefit of broadly engaging both the innate and adaptive immune responses to better simulate the immunity to natural infection. Replication-competent vectors have additional immunogenicity advantages over replication-defective vectors, because more prolonged Ag expression and more diverse stimulation of TLR pathways often translate into better Ab production and more durable immune responses.

CHIMERIC LIVE VIRUS REASSORTANT AND RECOMBINANT VACCINES

Two major platforms have emerged to create chimeric viruses. One is based on reassortment of genes that occurs in segmented RNA viruses and is used in two currently licensed vaccines. The other utilizes reverse genetic systems developed to make molecular clones of viruses with nonsegmented RNA genomes. Live attenuated chimeric virus vaccines are distinguished from live viral vectors because the viral vaccine Ag being expressed is derived from the same virus family and replaces the homologous protein from the virus that supplies the coding and noncoding regions constituting the replication-competent particle.

The rhesus and bovine rotavirus vaccines are examples of live attenuated chimeric viruses produced by reassortment. The chimeric viruses contain the attenuating background of the rhesus or bovine rotavirus plus the gene for a human rotavirus VP7 surface protein. Similarly, the live attenuated influenza virus vaccines are chimeric viruses that can be antigenically updated by replacement of the HA and NA genes of the attenuated donor virus with those of a new epidemic or pandemic virus. This process was utilized in the response to the 2009 H1N1 pandemic. While the replication of A/California/7/2009 H1N1-like isolates in eggs was relatively low, the chimeric live virus produced as FluMist had outstanding growth properties that facilitated production.

Construction of recombinant live attenuated chimeric virus vaccines by gene replacement in molecular clones has most commonly utilized flaviviruses and paramyxovirus backgrounds. For flaviviruses, a live attenuated virus vaccine candidate for JEV has been made by the replacement of genes encoding the membrane precursor (prM) and envelope (E) proteins of the attenuated yellow fever virus (YFV) vaccine with those from an attenuated strain of JEV. The resulting

JEV-YFV antigenic chimeric recombinant vaccine candidate was attenuated and immunogenic *in vivo*.¹⁷³ Both components of this chimeric virus came from attenuated viruses. It has now been evaluated in advanced clinical trials²⁸⁶ and is being submitted for registration.¹⁷⁵ Chimeric recombinant candidate vaccines have been made between a naturally attenuated tick-borne flavivirus (Langat virus) and a wild-type mosquito-borne dengue type 4 virus (DENV-4), and the resulting recombinant was found to be significantly more attenuated than its tick-borne parent virus for mice.³⁵⁵ This is an example of an attenuating effect that stems from partial incompatibility between the two components of the chimeric virus. Another strategy is being pursued for the production of a tetravalent dengue virus vaccine in which a DENV-4 background containing an attenuating deletion mutation in the 3' noncoding region is used to construct antigenic chimeric viruses containing the surface proteins of other dengue serotypes.²⁷⁸ Alternatively, the 3' attenuating mutation is reproduced in the other serotypes. Chimeric flavivirus constructs appear to be a stable and effective vaccine platform for these types of viruses. Tetravalent, live attenuated dengue vaccines based on either the attenuated DENV-4 background or the chimeric YFV expressing prM and E from each serotype are immunogenic in humans and are being evaluated in advanced clinical trials.^{175,307}

A chimeric virus containing the HN and F surface proteins of parainfluenza virus type 1 (PIV1) substituted for those of an attenuated parainfluenza virus type 3 (PIV3) virus has been constructed and shown to be attenuated and protective in experimental animals.⁴²¹ Both bovine and human PIV3 chimeras are being pursued to make vaccines against several other paramyxoviruses including PIV1, -2, and -3, RSV, metapneumovirus, and measles virus. Both human and bovine PIV3 are very amenable to use as a background for chimeric paramyxovirus vaccines; however, other paramyxoviruses are also being developed as vaccine vectors including Sendai virus, NDV, canine distemper virus, and measles virus.¹⁹⁸ Paramyxoviruses have also been constructed as vectors to deliver vaccine Ags from unrelated viruses such as HIV or Ebola.¹⁰⁷

POXVIRUS VECTORS

Vaccinia virus is the most commonly used recombinant vector to date.²⁹⁵ Poxviruses have large genomes into which a variety of foreign viral genes can be inserted and expressed without seriously compromising the capacity of vaccinia virus to replicate. Recombinant vaccinia viruses expressing the surface protein(s) of a large number of viruses have been constructed and are shown to be protective in experimental animals. Polyvalent live vaccinia virus recombinants have been used to successfully immunize experimental animals, even in the presence of immunity to one of the foreign viral Ags,¹³² and vaccinia-rabies virus recombinants are being used to control rabies in foxes³⁴² (e-Table 14.3). Recombinant vaccinia has been evaluated in clinical trials,^{158,160,161} although they are not sufficiently attenuated for use in immunocompromised hosts^{129,172,365} and are complicated by other idiosyncratic side effects such as myopericarditis.¹⁸ However, new versions of attenuated replication-competent poxvirus vectors such as the Tianan strain of vaccinia have been constructed as candidate HIV vaccines and are currently being evaluated in clinical trials in China.¹⁰³

HERPESVIRUS VECTORS

Herpesvirus vectors have been developed using HSV-1, EBV, CMV, and some animal alphaherpesviruses. The primary advantages of this vector system are the capacity to package up to 100 kb of foreign DNA and the potential for long-term gene expression from latent episomal DNA that can be present in both neuronal and nonneuronal cells.⁵² Herpesviruses have tropism for a wide variety of cells and are efficient at cell binding and attachment even at low particle-to-cell ratios. Vectors can also be pseudotyped to help target delivery into selected host cells. They can be given mucosally as well as parenterally and can be engineered to eliminate immune evasion genes such as the HSV-1 ICP47 that interferes with the transporter associated with antigen processing (TAP) to diminish MHC class I presentation. Live herpesvirus vectors can be attenuated to avoid vector-mediated disease and can also be made replication defective (see later discussion). Because HSV is ubiquitous, a potential disadvantage for this approach is that pre-existing Ab to the vector may diminish immune responses to the transgene product. In a murine model, it was shown that pre-existing HSV immunity did not alter the Ab or proliferative responses to recombinant protein encoded by the HSV vector.⁴⁷ Using animal herpesvirus vectors may be an alternative approach to circumvent the potential problem of pre-existing immunity to the vector, although replication is severely restricted when species barriers are crossed.⁴²⁹ There is a licensed veterinary vaccine for Marek's disease in chickens based on this technology (see e-Table 14.3), and this technology has also been applied in HIV vaccine development. Initially, it was shown that replication-competent HSV vectors expressing Env and Nef showed partial protection against challenge with SIVmac239.³⁰⁸ Subsequently, rhesus CMV vectors were constructed expressing Env, Gag, Pol, and Rev/Nef/Tat. Animals immunized with either recombinant CMV vectors alone or primed with CMV and boosted with recombinant adenovirus (rAd) vectors had significant protection from a SIVmac239 mucosal challenge. The correlate of protection is thought to be persistence of tissue-resident effector memory CD8 T cells, sustained by the persistence of the vector.¹⁸⁵

RHABDOVIRUS VECTORS

VSV has been engineered to serve as a vector for recombinant gene delivery. Recombinant VSV can be produced at high titer, is relatively stable, has broad tropism, and can be given mucosally.²²⁰ VSV is a rhabdovirus and is known to have neurovirulence. Therefore, extensive work has been done to attenuate the parent vector by altering the gene order and by truncating the cytoplasmic tail of the major surface glycoprotein.³⁶⁰ Gene delivery and subsequent immune responses to the recombinant gene product are potent,¹⁷⁹ and rhesus macaques immunized by a VSV vector expressing Env and Gag have been protected from SHIV challenge.³⁷⁶ Replication-defective VSV vectors have also been developed (see later discussion).

LIVE ADENOVIRUS VECTORS

The live adenovirus vaccine for serotypes 4 and 7 is a licensed and highly effective vaccine that is administered mucosally. Therefore, it has ideal properties for a gene-delivery vehicle and has been developed as a candidate HIV-1 vaccine.^{256,347} The advantages are the track record of the vector for both safety and efficacy, as well as the potential for delivery in capsules to the lower intestinal tract.^{174,416}

PICORNAVIRUS VECTORS

Poliovirus vectors have been developed that can express recombinant foreign proteins that are excised by the virus-encoded protease after translation of the recombinant polypeptide.¹⁵ The major advantages of this approach are the long history of successful vaccination with the vector and the capacity for oral delivery and induction of mucosal immunity. The major disadvantage of this system is the relatively small packaging capacity (~200 aa) that requires a library of recombinant viruses in the vaccine to deliver large Ags. There is also the concern of reversion to neurovirulent forms of poliovirus, although there are new design approaches that can probably overcome this problem by manipulating the fidelity of the poliovirus polymerase¹⁹ or substituting the internal ribosomal entry site (IRES) in the 5' untranslated region with a similar stem-loop structure from rhinovirus.⁵⁷ Other issues complicating the use of live poliovirus vectors include pre-existing immunity against the vector in vaccinated persons and the recommendation to only use inactivated poliovirus vaccine in the United States. Although the global eradication campaign seeks to eliminate the need for polio vaccination, as with variola, as long as the virus remains in freezers or the sequence is available in databases, the idea of maintaining immunity to polio in the general population by using poliovirus as a vector for other pathogens has merit. Enteroviruses and rhinovirus vectors have been developed using similar technology and to target different mucosal inductive sites, and new innovations such as removing part of the capsid gene can provide a larger coding region for the vaccine Ag.^{108,298}

BACTERIAL VECTORS

Bacterial vectors have also been used to deliver viral Ags. Recombinant bacilli Calmette-Guérin (BCG) has received the most attention. Some advantages of BCG as a vector include (a) its safety record after administration to millions of persons, particularly in developing countries; (b) its persistence and therefore prolonged Ag production that may provide a more durable immune response; (c) its potential for mucosal administration; (d) its innate chemical composition that provides an adjuvant effect through TLR-1, TLR-3, TLR-4, and possibly other pattern recognition receptors; and (e) that immunity against tuberculosis could be a by-product of immune responses to the vector. Advances in mycobacterial genetics have made construction of recombinant vectors feasible,³⁸⁶ and because of the large capacity for accepting foreign genes, co-expression of cytokines and other immunomodulators is possible.^{11,309} In addition, discoveries about how mycobacteria inhibit apoptosis of macrophages to delay immune-mediated clearance have led to the development of attenuated mycobacteria for vaccination against tuberculosis. New promoters, other vector design modifications, and combining with other modalities may further enhance immune responses to the foreign gene products.³⁷⁵ Other bacterial vectors that have been considered for delivering viral Ags include lactobacilli, salmonella, shigella, and listeria. The salmonella and shigella vectors have also been designed to deliver the gene-based vaccine Ag by plasmid and thereby combine mucosal delivery and adjuvanticity with authentic glycosylation of the gene product.¹³⁶ This concept has been tested in early-phase clinical trials to express an HIV-1 envelope protein, although there was poor immunogenicity.

Replication-Defective Vectors

Replication-defective virus vectors have had genes deleted that are essential for replication *in vitro* or *in vivo*. Replication-defective viruses can replicate to high titer in cell lines engineered to express the missing protein that would be encoded by the deleted gene. The viruses produced in such complementing cells can attach and deliver their genetic payload to cells *in vivo* but are unable to replicate. Such vectors undergo an abortive infection *in vivo* but express the foreign protein during this abortive infection and can thereby induce both the humoral and cellular arms of the immune response. Non-replicating vectors do not retain the virulence of the original agent from which they were derived and would be expected to be safe even in hosts with compromised immune systems, should they encounter the vector. Many vectors retain the antigenicity of structural proteins from the original agent. This raises two issues. The first is reactogenicity. Many vectors can trigger innate immune responses that cause local and systemic reactions in the vaccinee. This is an advantage from the perspective of adjuvant activity but can be limiting at higher doses of the vector. The second is pre-existing immunity to the vector. If the vector is derived from an agent to which the host has had prior exposure, the pre-existing Ab can dampen the immunogenicity of the delivered vaccine Ag. Vector-based vaccines are of particular value when the vaccine target is a virus for which live attenuated or whole inactivated virus vaccines are not considered for safety or other reasons. Vectors have added value when the vaccine strategy is focused on inducing CD8 T-cell responses because they deliver the vaccine Ag to the cytoplasm, allowing access to the MHC class I processing pathway for Ag presentation. Because this characterizes the current strategies for HIV vaccine development, most vector-based vaccine strategies have been evaluated for the induction of protective immunity against lentivirus infection. Therefore, antiviral vaccine vectors will be discussed primarily in the context of HIV vaccine development even though they are also being developed for many other antiviral vaccine programs.

The regulatory approval pathway for vector-based gene delivery will involve scrutiny around issues such as integration, recombination, reversion to replication competence, and reactogenicity. The origins of many vaccine vectors are from the field of gene therapy, and some of the clinical events associated with gene therapy trials still affect the evaluation of vaccine vectors. For example, the 1999 death of a teenager in a gene therapy trial at the University of Pennsylvania prompted extensive reviews of safety data from both human and animal studies of vector-based gene delivery. The 18-year-old patient, who had a rare liver disorder called *ornithine transcarbamylase deficiency*, died after receiving a large dose (3.8×10^{13} particle units [PU]) of E1/E4-deleted serotype 5 adenoviral vector directly into the liver through the right hepatic artery. The death was most likely attributable to an adenovirus-induced cytokine storm with subsequent disseminated intravascular coagulation, acute respiratory distress, and multiorgan failure.³ This incident compels a cautious approach to dose and route evaluation of any antigenic substance but particularly vector-based products. Another gene therapy incident involved a retrovirus vector used to successfully treat children with X-linked SCID. After 3 years, some of the children developed leukemia associated with the integration of vector DNA into the LMO2 proto-oncogene locus.^{176,177}

ADENOVIRUS VECTORS

Replication-defective rAds exhibit characteristics that make them ideal vaccine vector candidates, and substantial resources are being invested to develop safe and immunogenic rAd vaccines for infectious agents including HIV, Ebola, plague, anthrax, influenza, tuberculosis, and malaria.²⁵ These vectors possess desirable qualities for use in vaccination strategies, including efficient transduction of host cells, limited duration of gene expression, vector nonpersistence, the ability to rapidly induce both humoral and cell-mediated immunity, induction of innate immune responses that may provide an adjuvant effect, relatively high stability, and ability to scale up production for manufacturing purposes.²⁵ Most rAd vaccine candidates are replication-defective owing to a deletion of the E1 region. Some vectors have additional deletions of E3 and E4 to increase capacity for gene insertion and to further reduce the chance of recombination in the packaging cell line to form replication-competent adenovirus. Deletion of E4 also prevents transcription of adenoviral genes encoding structural proteins to reduce antigenic competition with the vaccine Ag. Complementary human embryonic cell lines such as PER.C6²⁵⁸ or 293-ORF6⁴⁸ are used to package the deficient rAd *in vitro* and allow large-scale production. Pre-existing immunity to a given adenovirus serotype has been shown in animal models and in human clinic trials to diminish the immunogenicity of the vaccine Ag. Adenovirus serotype 5 (Ad5) immunity has a high prevalence, particularly in developing countries.²²⁹ Although Ad5 has been commonly used in the initial studies, there are 51 human adenovirus serotypes, and many have now been engineered to express foreign genes. In addition, new vectors have been constructed from adenoviruses derived from chimpanzees and macaques that have favorable properties and will provide options to avoid pre-existing vector-specific immunity. An alternative to using a rare serotype rAd vector is to construct chimeric vectors. For example, adenovirus vectors have been developed in which the shaft and knob portions of the fiber proteins are exchanged.⁴⁶⁰ Another novel approach involved making hexon loop chimeras in which the neutralizing targets in hexon are exchanged for those of an uncommon adenovirus serotype.⁴¹⁴ A mucosal route of administration is another potential option for overcoming pre-existing vector immunity, with the added advantage of better induction of immunity in the mucosal compartment. This may be particularly important for inducing immunity against viruses that primarily enter the host through a mucosal surface such as HIV and influenza. Replication-defective rAd has been successfully given mucosally without adverse reactions,⁴³⁴ even though one study in mice showed that intranasal administration could result in Ag expression in the olfactory bulb.²⁴⁵ The effects of pre-existing immunity to the vector can also be partially overcome by increasing the dose or by priming with a heterologous vector expressing the vaccine Ag of interest. Finally, one can avoid pre-existing immunity by carefully selecting the target population. For example, children between 6 months and 2 years of age are Ad5 seronegative, which makes recombinant Ad5 vectors a viable choice for immunization of that age group.

The Step study was a phase IIb trial that evaluated E1-deleted recombinant Ad5 vectors expressing HIV-1 Gag, Pol, and Nef in individuals at high-risk of HIV infection. It was stopped prematurely in 2007 because there was a higher frequency of HIV-1 infections among vaccinees than placebo

recipients.⁴⁹ The increased rate of infection was associated with being uncircumcised and with pre-existing Ad5 Ab. The biological basis for this outcome is not known. HIV-1 vaccine clinical trials utilizing rare serotype rAd vectors and recombinant Ad5 vectors (E1, E3, E4-deleted expressing HIV-1 Env, Gag, and Pol) in heterologous prime-boost combinations with DNA vaccines are still in progress.

ADENO-ASSOCIATED VIRUS VECTORS

Adeno-associated virus (AAV) vectors are unique because the wild-type virus itself is replication-defective and requires the presence of wild-type adenovirus as a helper virus to propagate. The vector is very simple and contains the promoter, foreign gene, and polyadenylation sequence surrounded by two short noncoding inverted terminal repeats from AAV. No genes from the wild-type AAV are included in the vector. Particles are produced in a packaging cell line that provides the AAV structural proteins. The AAV capsid induces an immune response, and as with other vectors, anti-AAV Ab can diminish immune responses to the foreign gene product expressed by recombinant AAV vectors. Using alternative capsid serotypes and incorporating immune modulators may overcome any limitations posed by pre-existing AAV immunity or allow heterologous boosting and further amplification of immunogenicity induced by primary vaccination. Transduction of muscle cells and APCs is efficient, and expression can be prolonged. A single dose of recombinant AAV has been shown to induce both humoral and cellular immunity sufficient to control SIV infection in macaques.²⁰⁵ AAV-transduced cells achieve persistent gene expression by delivering concatameric circular episomes that remain transcriptionally active, and there is no evidence for integration.³⁹⁴ Long-term episomal gene expression has been uniquely demonstrated by delivering neutralizing Ab genes to muscle cells in rhesus macaques and achieving sufficient titers in serum to protect against SIV challenge.²⁰⁶

ALPHAVIRUS VECTORS

Alphaviruses such as Venezuelan equine encephalitis (VEE) virus, Sindbis virus, and Semliki Forest virus (SFV) have been modified to produce three distinct types of immunogens. All take advantage of the alphavirus replicon that is a minimal genome with replication origins and packaging signals. The vectors include the alphavirus nonstructural genes including the replicase and the subgenomic promoter upstream of a foreign gene that replaces the genes encoding alphavirus structural proteins. The replicon itself can be injected as either plasmid DNA or as naked RNA. Alternatively, helper cell lines can be constructed that provide the structural gene products needed for packaging of replicons and particle assembly of nonpropagating vectors.¹⁴⁰ These replication-defective viral particles are extremely efficient in targeting APCs, particularly dendritic cells, and because of the amplification of the RNA, they achieve high-level expression of the foreign protein. They have induced significant humoral and cellular immune responses to a variety of viral proteins in animal models,^{192,207,361} and a VEE vector expressing HIV Ags has advanced into clinical trials.⁴⁵¹ The immunogenicity of the VEE vector is in part owing to its tropism for dendritic cells. When minor changes are made in the envelope protein to diminish dendritic cell entry, the induction of immune response is compromised.²⁵⁹ One unique property of VEE vector-induced immunity is that parenteral immunization has

been shown to induce mucosal IgA responses.¹⁸⁶ The mechanism underlying this phenomenon relates to the rapid and dramatic effect that the VEE particles and replicons have on the systemic innate immune response²²⁷—an effect that occurs in the first 24 hours after inoculation.⁴²⁴ Because the stimulation of the innate immune system by VEE replicons also appears to enhance adaptive immune responses, replicons that do not express a vaccine Ag can be used as an adjuvant to enhance the protective response to subunit vaccines.⁶¹

HERPESVIRUS VECTORS

Replication-defective HSVs have been produced in a manner analogous to that of the E1A-deficient adenoviruses—that is, they have had one or more genes deleted that are essential for replication; however, replication *in vitro* is supported in a cell line that constitutively expresses the essential protein needed for replication.^{100,289} In contrast to the E1-deficient adenoviruses, the replication-defective HSVs are being developed as vaccines to protect against disease caused by HSV itself, as well as a vector to deliver foreign viral proteins. One potential advantage of herpesvirus vectors is persistent Ag production that may be required for the optimal induction of cellular immune responses. Another approach to vector construction is to package replication-defective HSV amplicons in HSV particles using bacterial artificial chromosome (BAC)-encoded helper viruses with deleted packaging sequences resulting in foreign gene expression without the influence of any residual HSV genes.¹⁵⁴

POXVIRUS VECTORS

Attenuated replication-defective poxvirus vectors have been developed to address the known complications of vaccinia virus in immunocompromised persons. The most developed vectors include MVA, avipox (canarypox and fowlpox), and NYVAC (deliberate deletion of 18 genes associated with virulence).³³⁸ MVA was derived by more than 500 passages in chick embryo cells^{266,280} and has been evaluated as a vaccine vector for a variety of viral Ags. MVA is a highly attenuated host-range mutant that replicates well in avian cells and has limited replication in BSC-40 and baby hamster kidney (BHK) cells but does not propagate in most mammalian cells.^{39,60,113} MVA is nonpathogenic in immunocompromised hosts and has been administered to large numbers of humans without incident.^{267,410,449} Attenuation of the MVA recombinant resulted from the loss of nearly 30 kb of genome including genes for immune evasion and host range during its many passages in embryonated eggs.¹⁶ The use of avian poxviruses, referred to as avipox viruses, as vectors represents a second type of host-range restricted poxvirus vector. Avipox viruses are naturally occurring host-range restricted viruses that are replication-deficient in mammalian cells and mammal hosts.³³⁸ Each of these poxvirus vectors has the property of efficient replication *in vitro* in avian cell culture but restricted replication in primates. Avipox vectors have an added advantage because pre-existing immunity to vaccinia does not impact vector delivery. Poxvirus vectors have the following advantages: (a) thermostability, (b) the history of being associated with the extraordinary success of the smallpox eradication campaign, (c) large packaging capacity for foreign genes, and (d) lack of persistence or genomic integration. The major disadvantages are that (a) attenuated vectors are grown in primary cell lines (chicken embryo fibroblasts),

and production is difficult to scale up; (b) the foreign gene insert is sometimes unstable; and (c) poxviruses are antigenically complex, and there may be competition between the vector and the inserted gene products for Ag processing and presentation.

After extensive phase I and phase II evaluation,^{152,352} a recombinant canarypox vaccine was evaluated in RV144—a controversial phase III efficacy study.⁵¹ This landmark study provides a benchmark as the first demonstration of efficacy for an HIV vaccine.³⁶⁶ A general population cohort of 16,402 people in Thailand was enrolled in the study and randomized 1:1 vaccine to placebo recipient. Vaccinees received intramuscular injections of a recombinant canarypox vector expressing Env, Gag, and parts of Pol and Nef given at 0, 1, 3, and 6 months and rgp120 formulated in alum given at months 3 and 6. At 18 months, 74 infections had occurred in placebo recipients, and 51 infections had occurred in vaccinees, which was statistically significant. A similar rgp120 did not protect men-who-have-sex-with-men (MSM)¹⁴⁸ or intravenous drug users (IVDU)³⁵³—populations with much higher incidence. The immune correlate of protection is not yet defined; however, protection appears to be temporally associated with serum Ab titers, even though vaccinee sera does not neutralize commonly transmitted strains using traditional assays.

Limitations of Gene-Based Vectors

It is beyond the scope of this chapter to cover the growing list of potential vectors to deliver genes encoding viral Ags that may be considered for future vaccine development. For example, arenavirus¹³¹ and lentivirus¹⁰² vectors have not been discussed here, and reverse genetic systems have been developed for other virus families²²⁵ that will make recombinant vector development feasible. Each system has a unique set of properties that should be considered when devising a strategy for a particular pathogen. One of the primary considerations is seroprevalence for the vector in the target population. Pre-existing vector-specific immunity can affect both safety and potency of the vaccine. This may be a problem if there is natural immunity to the vector or if competing vaccine programs for other important pathogens converge on the same vector platforms. There are several factors involving safety, Ag selection, immunogenicity, manufacturing, and stability that are important to consider when developing a vector-based vaccine strategy that are pathogen and target population specific (see e-Table 14.2).

Viral Vectors as Vaccines Against the Virus from Which the Vector Was Derived

A practical by-product of the development of gene-based replication-defective viral vaccine vectors is that the vector itself may serve as a novel vaccine platform for the virus from which the vector was derived. The most advanced examples of this are the poxvirus vectors such as MVA or NYVAC. These have been evaluated as candidate smallpox vaccines in clinical trials using replication-competent vaccinia (Dryvax) as a surrogate challenge.^{139,341} This type of approach has also been proposed for herpesviruses¹¹⁶ and adenoviruses. Using the viral vector creates the opportunity to express additional viral Ags⁹ or immunomodulatory proteins such as cytokines⁷⁰ that could provide adjuvant effects and increase immunogenicity compared to the live attenuated virus platform. Another advantage of this approach is that the vector delivers the antigenic

complexity of a live attenuated virus vaccine with a more favorable risk profile because of lack of replication. In addition, the vector provides more options for achieving robust manufacturing capacity, although this is often a challenge for live attenuated viral vaccines.

VACCINE FORMULATION AND DELIVERY

Adjuvants

Adaptive immune responses are controlled by the amount, duration, and formulation of the Ag in conjunction with innate immunity. The Ag sequence and structure determines specificity; however, the adjuvant and context of delivery and Ag presentation determine the composition, location, kinetics, and magnitude of vaccine-induced immune responses (e-Fig. 14.11). Although specificity is a property of the adaptive immune response, many adjuvant effects are mediated by the innate immune system. The most potent and broad-based adaptive immune responses are induced by replication-competent virus vaccines and gene-based viral vectors. These vectors provide efficient Ag presentation and inherently stimulate innate immunity through a variety of signaling pathways, thus limiting a requirement for exogenous adjuvants. By contrast, inactivated virus vaccines, purified viral proteins, or peptide Ags by themselves have relatively weak immunogenicity in a naive host. There are several reasons why replication-competent viral vaccines and gene-based vectors are inherently more immunogenic than inactivated virus or subunit vaccines. First, gene expression provides an ongoing source of the relevant protective Ag that is amplified through replication beyond the dose contained in the original inoculum. Second, Ags produced during transcription in the host cells have native quaternary and multimeric particulate structures and authentic posttranslational modifications. Third, replication-competent viruses and gene-based vectors can broadly engage multiple distinct innate immune and Ag presentation pathways. Indeed, a major advantage of live or attenuated viral vaccines is that expressed antigenic epitopes are processed efficiently through both MHC class I and II pathways. This mechanism contrasts with that of inactivated vaccines where Ag processing is mostly limited to MHC class II presentation, which elicits CD4 T-cell responses but is limited for generating CD8 immunity. Finally, PAMP recognition receptors are engaged on the cell surface, in endocytic vesicles, and in the cytoplasm with live vaccines (e-Fig. 14.12). Therefore, adjuvants are needed to compensate for the diminished immunogenicity of vaccines that are not transcriptionally active in host cells by recruiting additional signaling pathways to activate innate immunity, promoting APC maturation and co-stimulation, and prolonging Ag persistence.

Empirically Derived Adjuvants

Traditionally, adjuvants have been derived from natural products empirically found to have immunostimulating properties. Adjuvants can improve immunogenicity by optimizing the duration of Ag presentation through a “depot” effect and/or through enhancing certain innate stimulatory pathways. It was first discovered that bacterial toxins were more protective when mixed with other substances.³⁶² A prototypic adjuvant used exclusively in laboratory research is Freund’s adjuvant prepared from mycobacterial cell walls. A modern version of IFA

(Montanide ISA-51) is a water-in-oil emulsion composed of mineral oil mixed with the surfactant mannose monooleate in a 1:1 ratio with the aqueous phase. Although vaccines formulated with mineral oil have been administered to more than one million people since 1945, with the emergence of aluminum-based adjuvants, they fell out of favor because of the reactogenicity profile and potential for causing sterile abscesses.¹⁶⁴ They are still frequently used in the context of therapeutic vaccines.

There are two currently licensed adjuvants in the United States for human use in preventive viral vaccines: alum and a combination of alum+MPL. Alum is derived from aluminum hydroxide or aluminum phosphate and is formulated as a gel or used to precipitate protein Ags to create aggregates. It functions as a short-term Ag depot in which Ag that is electrostatically bound to alum is slowly released at the site of inoculation. More recent studies have shown that some of the adjuvant activity conferred by alum is through activation of the “inflammasome” innate signaling pathway.¹¹⁹ Alum has been the standard adjuvant used in licensed vaccines for several decades. All currently licensed inactivated viral vaccines and hepatitis B VLPs are formulated with alum. Gardasil, the Merck HPV VLP vaccine, is also formulated with alum. More recently, Ab responses can be improved by combining additional immune stimulatory molecules to alum. Indeed, AS04 (Adjuvant System 04, GlaxoSmith-Kline, London, UK) is a combination of alum and a modified synthetic form of MPL, which is a key component of lipopolysaccharide (LPS) that is the ligand for TLR-4. Cervarix, the HPV VLP from GlaxoSmithKline, is formulated with AS04 and is the first adjuvant containing a TLR ligand to be approved for use in humans. The MPL-based adjuvants when combined either with alum (AS04) or with QS21 (AS02) have been shown to have a significant dose-sparing effect and may have additional advantages in terms of the speed and durability of the humoral responses. Formulations that include MPL also stimulate IFN- γ , producing CD4 T-cell responses that may have additional benefit.³¹⁶

After alum, the other most widely used adjuvant in humans is MF59. MF59 is a squalene oil-in-water squalene emulsion that is licensed for human use in Europe. MF59 was designed originally to provide an Ag depot from which Ag would be slowly released as the biodegradable oil was metabolized or removed by macrophages, and as a vehicle for the immunostimulant muramyl tripeptide-phosphatidyl ethanolamine (MTP-PE), a derivative of muramyl dipeptide, the active component of the mycobacterium cell wall fraction in Freund's complete adjuvant. However, clinical studies in humans indicated that MF59 itself was as immunostimulatory as MF59/MTP-PE with less toxicity.¹⁶² Its adjuvant effect is not TLR dependent, but there is evidence that MF59 has some innate immune stimulatory capacity. More than 45 million doses have now been given to humans formulated with seasonal influenza vaccines. MF59 is dose sparing, and clinical studies with H5N1, H1N1, or seasonal trivalent influenza vaccines show that protective levels of immunity can be achieved with as little as 3.75 μ g of vaccine Ag.⁷⁹ A similar squalene oil-in-water emulsion (AS03) has achieved similar dose-sparing effects when formulated with influenza Ags.³¹⁷ MF59-formulated influenza vaccines also result in Abs with greater cross-reactivity and greater avidity to conformational epitopes than

alum-formulated vaccines in head-to-head comparisons.²¹⁸ As with alum, MF59 tends to promote Th2 responses.⁴³²

QS21, the active ingredient of immune stimulating complexes (ISCOMs), was discovered in the bark of *Quilaja saponaria*, Molina (soap bark tree). It was named for the tree's scientific name and for being the 21st peak on the high-performance liquid chromatography analysis of the bark extract. The basis for its adjuvant properties is not known.

Rationally Designed Adjuvants

As discoveries were made in the 1980s and early 1990s about the regulation of immune responses by cytokines,²⁹⁴ chemokines,⁷ and co-stimulatory molecules,³⁹² a more targeted molecular approach was taken to vaccine adjuvants. The trend during the 1990s was to attempt to build the optimal adjuvant effect one cytokine at a time and try to precisely control the processes of cell activation and differentiation.^{251,420} This approach may still be possible but has underestimated the complexity of the molecular milieu required to produce a specific effect, and also has underestimated the complexity of effector phenotypes and the importance of timing involved in the successive waves of regulatory events participating in nascent immune responses. For example, in a study evaluating HIV Ags delivering by DNA together with an IL-2-Ig fusion protein also expressed as a plasmid, it was found that the cytokine only provided an adjuvant effect if delivered 48 hours after the vaccine Ag.²⁰

More recently, the understanding of how PAMPS²⁰³ are recognized has helped to explain the molecular basis for some traditional adjuvants and has resulted in better characterized products that are now being developed as vaccine adjuvants. PAMPS are recognized by TLRs—a family of type 1 integral membrane proteins—present on plasma membranes or within endosomes.²⁷⁶ Ligands for any of the 11 currently known human TLRs can produce an integrated set of responses by APCs and other components of the innate immune system to stimulate adaptive immune responses (Chapter 8). Using TLR ligands instead of individual cytokines to adjuvant vaccine-induced immune responses helps to avoid the unanticipated problems that arise when using individual molecular adjuvants in isolation, providing a more authentic stimulus for the host to decide what pattern of cytokines, chemokines, and co-stimulation will be needed for a particular immune response. Empirically developed adjuvant products such as muramyl dipeptide derivatives or MPL are known to stimulate TLR-2 and TLR-4, respectively. Components of live and inactivated virus vaccines such as double-stranded RNA and single-stranded RNA are known to stimulate TLR-3 and TLR-7/8, respectively. Experimental adjuvants such as PolyI:C (TLR-3 agonist) and imidazoquinoline compounds (imiquimod or resiquimod TLR-7/8 agonists) are being explored to mimic these features of live virus infection. Palindromic CpG motifs present in bacterial DNA that are ligands of TLR-9 are also used as experimental adjuvants.

It is beyond the scope of this chapter to review all of the ways that cytokines, chemokines, and activation of TLR signaling pathways are being explored in antiviral vaccine formulations. As described previously, the discovery of PAMP recognition receptors provides an explanation for the activity of some empirically developed adjuvants (e.g., TLR-2 and TLR-4 agonists) and a platform for the rational design of future vaccine adjuvants.

Delivery Vehicles

Delivery of vaccine Ag can determine the immunological compartment that is stimulated and influence the types of APCs that process the vaccine Ag. Many delivery vehicles are formulated with adjuvants or have innate adjuvant properties; however, in this section the term will refer to approaches for transporting Ag to a particular location. A delivery vehicle may allow the mucosal delivery of an Ag that could otherwise only be given parenterally. Alternatively, a delivery vehicle could function as a way of co-delivering a mixture of Ags and adjuvant, produce a depot effect, or otherwise control the timing of release of Ag. More recently, vaccine delivery vehicles have been designed to carry Ag into particular subcellular compartments with the intent of stimulating specific immune responses by accessing distinct Ag processing pathways.

Lipid-Based Carriers

Many virus surface proteins are spatially oriented in lipid envelopes, and that is one rationale to use lipids in the formulation of virus vaccines. Another is that the Ag may be protected by the lipid and allow delivery through harsh environments such as the gastric mucosa or blood, or promote a depot effect when injected. Liposomal vaccine formulations may facilitate DNA transport into target cells and have been used extensively for transfection of cells *in vitro*. Liposomes are vesicles with a roughly spherical lipid bilayer surrounding an aqueous center.¹²⁸ If virus-derived proteins are inserted into the membranes (proteoliposomes), they are often referred to as virosomes. Liposomes have been used to deliver peptides, proteins, whole virus, and DNA with and without adjuvants and can be designed to target or co-stimulate selected APCs. The intent is to produce an inert particle that concentrates in the target organ of interest and then releases its payload. Typically, when used for purposes of DNA delivery, cationic lipids are used in the liposome formulation to improve the interaction with the negatively charged nucleic acid. The lipid composition of the liposome can be modified to affect charge, pH sensitivity, thermal stability, and fusogenicity to control release of the products. Virosomes are used in licensed products (non U.S. products) to deliver vaccine Ags for influenza and hepatitis A.²⁹² More elaborate virosomes in which the proteoliposome is built around a polystyrene bead are being developed as a candidate HIV-1 vaccine, using the scaffolding of the particle to produce more stable conformations of the envelope glycoprotein.¹⁷¹ As a natural source of liposomes, exosomes are 50- to 90-nm vesicles produced by an endosomal process in which vesicles bud into endosomes (multivesicular bodies) and are then secreted from APCs. Interestingly, these exocytic vesicles contain many of the proteins involved in Ag presentation, including MHC and co-stimulatory molecules.²³⁸ In addition, they have lipid content similar to many enveloped viruses and lipid rafts with high cholesterol content.¹⁵⁷ ISCOMs are another lipid-based vehicle for delivering vaccine Ag. They are 40-nm cage-like structures formed by a complex mixture of lipids and saponins that can be formulated with viral Ags.⁶ ISCOMs are able to deliver proteins or peptides to the cytoplasmic compartment, where they can be processed to activate CD8 T cells, and this has also been demonstrated in clinical trials of HPV and HCV vaccine candidates.³⁸⁷ ISCOMs also have adjuvant properties derived primarily from the saponin component QS21, as described previously.

Synthetic Particles

Synthetic polymers have been used in creative ways to contain or hold vaccine Ags for presentation to the immune system. Microparticles are made from biodegradable polymers complexed with viral Ags.⁹⁴ The primary polymer used is poly lactic-co-glycolic acid (PLGA), which can encapsulate DNA by itself or with multiple proteins, adjuvants, or other immunomodulators. PLGA has an extensive history of safety in humans because it is the polymer used in absorbable sutures. Some other advantages of microparticles (1 to 10 μm) include (a) preferential uptake through the phagocytic pathway of dendritic cells; (b) protection of the vaccine product from the environment, resulting in a slow-release depot effect³²⁴; and (c) a potential payload capacity that is higher than for liposomes or viral vectors. PLGA microparticles coated with cationic surfactants have also been used as a vehicle for DNA delivery by absorption of plasmid DNA to its charged surface.³²⁴ In general, these approaches have not produced the robust gene expression and immunogenicity needed for gene-based vaccination, and the formulations are being empirically modified. One approach has been to produce a hybrid polymer by combining PLGA with other substances such as poly- β amino ester to improve the sensitivity to pH change and more rapidly liberate the DNA.²⁵² Another approach for DNA delivery has been to use alternative polymers such as poly (ortho esters) (POEs), which had been developed for drug and peptide delivery.⁴⁴²

Nanoparticles also have been explored as vehicles to deliver DNA vaccines. Generally sizes of less than 200 nm (close to the size of many viruses) have been used, which are less likely to be forced into the phagolysosome pathway than microparticles. One approach has involved polylysine cationic polymers with imidazole side chains to facilitate escape from endosomes.²⁵³ Another utilizes an oil-in-water microemulsion to produce wax cationic nanoparticles⁹⁸ that can be modified to encapsulate DNA.³⁰⁰ Finally, nonionic block co-polymers have been used to deliver DNA vaccines with promising results in animal models but not in human trials.⁴⁰⁰

Synthetic self-assembling polypeptides can be used to display vaccine Ags on particles to achieve multivalency similar to the use of VLP as Ag scaffolds.³⁵¹ Another approach is to use self-assembling proteins from other (nonviral) biological sources such as the yeast protein Ty,²⁴⁴ although evaluation of these structures in human trials did not induce significant immune responses.⁴⁴⁷

Cell-based Carriers

Dendritic cells are important for Ag presentation, for initiating the innate responses, and for bridging the innate and adaptive immune systems to coordinate a comprehensive response to a virus infection. Therefore, they have been central to several vaccine development efforts. Not surprisingly, dendritic cells themselves have been used as the vehicle for Ag delivery. Autologous dendritic cells have been sorted, expanded *in vitro* with selected cytokines, pulsed with peptide, inactivated whole virus, or vectors and then reinfused into subjects.^{255,263,325} Another cell-based vaccine approach utilizes transgenic plants. Potatoes, lettuce, tomatoes, carrots, and corn have all been engineered to produce vaccine Ags that have been evaluated in clinical trials.⁴¹⁵ This technology is also in early stages but has partially overcome some of the initial theoretical concerns that delivery of edible vaccines would result in oral tolerance or

possibly result in food allergies to the carrier. A major advantage of transgenic plants is that production does not require an extensive physical infrastructure, and therefore manufacturing is inexpensive and easily distributed.

Conjugates

Vaccines derived by conjugating protein to carbohydrate have been extraordinarily successful for the control of encapsulated bacteria. The protein in this setting helps to redirect the Ag presentation so that alternative Ab isotypes are produced to control the bacteria. Because the carbohydrate structures of viruses are made by the host cell, they are not antigenic targets and often protect the virus from host immune defenses, as exemplified by the “glycan shield” of the HIV-1 gp120. Conjugates for viral Ags have typically been designed to carry the viral Ag into the cytoplasmic compartment of the APC so that processing and MHC class I presentation and CD8 T-cell activation can occur. This objective has been accomplished by using heat shock proteins (HSP70),⁶⁴ alpha-2 macroglobulin,²⁵⁰ and leader sequences that promote membrane translocation to help the protein directly enter the cytoplasm.^{189,372} Protein conjugate vaccines with Ab Fc receptors, CpG motifs, and TLR-7/8 agonists^{73,450} also have been used to improve the efficiency of uptake of viral Ags to dendritic cells. An additional approach is to target Ag directly to dendritic cells through incorporating the viral Ag into an Ab such as the DEC205 Ab conjugate that delivers Ag directly to dendritic cells.^{133,314} This provides an efficient *in vivo* approach for targeting dendritic cells instead of the *ex vivo* approach mentioned earlier, which may be limited to therapeutic vaccines for chronic virus infection and cancer.

Mechanical Devices

Currently licensed vaccines are given orally or by needle and syringe, aerosol, or bifurcated needle in the case of vaccinia. Future vaccines and adjuvants or immunomodulators may utilize more technically sophisticated devices such as microneedles²²¹ or micromechanical abrasion.²⁸² Other delivery devices have been adapted or developed in large part to address the need for improving the efficacy of DNA vaccines in humans. Needle-free injection systems such as Biojector or PowderJet have been used to deliver DNA vaccines in clinical trials,^{163,378,443} and in both animal models and humans, electroporation has been shown to improve Ag expression and immunogenicity of DNA vaccination.^{388,435} In addition, there continue to be new designs for delivery by traditional aerosol or needle and syringe devices that have been designed to improve effectiveness or safety. In particular, there are rapid advances in microneedle (<1 μm) technology in which arrays of needles made from a wide variety of materials (ranging from stainless steel to dissolving crystalline sugars) can effectively deliver vaccines.

Combination Approaches

Co-Delivery or Multivalent Vaccines

Co-delivery of vaccines has become a matter of practicality with more than 13 pathogens being targeted during the childhood immunization series alone. Therefore, combined vaccine formulations such as MMR (measles, mumps, rubella), the tetravalent product that includes varicella vaccine with the MMR combination, IPV (polio serotypes 1, 2, and 3), and influenza (B and A H3N2 and H1N1) are commonly used. Factors such as antigenic competition, interference, and

unanticipated adverse reactions need to be considered during the development of combination products.

Co-delivery of different vaccines against the same pathogen can sometimes augment immunogenicity. Simultaneous administration of two different influenza virus vaccines to elderly subjects—namely, an intranasally administered live attenuated⁴¹⁵ influenza A virus candidate vaccine and a parenterally administered licensed inactivated virus vaccine—induced greater resistance to illness than did administration of the inactivated virus vaccine alone.⁴³⁰ In this situation, the greater immunogenicity of the live virus vaccine in the respiratory tract coupled with the greater efficiency of the inactivated virus vaccine in stimulating systemic immunity appear to act in concert to optimize efficacy. A replication-defective HSV vaccine was found to be most immunogenic when administered by both parenteral and mucosal routes, indicating that the same vaccine preparation can also be given by a combination of routes to augment protection.²⁸⁹

Sequential Combination of Vaccines

Sequential combination of different vaccine modalities that focus on inducing immune responses to the same pathogen have recently been referred to as prime-boost strategies.³⁶³ This concept takes advantage of the memory inherent in the adaptive immune response by sequentially amplifying the response to selected Ags. This can be done with combinations of replication-competent or gene-based vectors with inactivated or subunit vaccine approaches or by heterologous vector combinations. Combining vaccine approaches has the potential for eliciting new components of the immune response and for broadening the response to new specificities and immunological compartments. Combining heterologous vectors has the added value of the boost, avoiding pre-existing antivektor immunity while amplifying the response to the expressed vaccine Ag.

Combination approaches can be used both for improving the safety of the booster vaccine and for improving immunogenicity beyond either approach alone. Polio vaccination is an example where using combined modalities improved both safety and immunogenicity. It is now recommended that only IPV be used for polio vaccination in the United States. Prior to this, sequential immunization with inactivated poliovirus vaccine followed by live attenuated virus vaccine was used as a safer alternative to OPV, the three-dose live virus vaccine. The combination approach provided immunity against the rare cases of vaccine-associated polio caused by the live virus vaccine and also primed for a booster effect from OPV, which expanded the immune response to the mucosal compartment. Thus, immunogenicity was optimized in the individual and herd immunity was provided to the population by inducing sufficient mucosal immunity in the gastrointestinal tract to prevent the spread of imported strains of poliovirus.^{284,350} Sequential immunization with a live attenuated alphavirus vaccine candidate followed with a boost with an inactivated virus vaccine induced higher levels of Ab than live virus alone.³⁵⁴ In the field of HIV vaccine development, a variety of prime-boost strategies have been evaluated. In some cases, priming has been done with a DNA or gene-based vector followed by subunit protein boost.^{82,90,160} This approach led to the first demonstration of efficacy against HIV acquisition using a recombinant canarypox vector expressing Env, Gag, and Pol boosted with recombinant gp120

protein.³⁶⁶ Other approaches have utilized heterologous vector combinations or DNA priming followed by gene-based vector boosting.^{13,183,230,396} These studies have shown that DNA priming followed by recombinant Ad5 boosting can protect against SIV infection in macaques and reduce viral load in vaccinated animals that experience breakthrough infections.²⁴⁷ This concept is being evaluated in HVTN 505, a phase IIb efficacy trial.

SUMMARY

Vaccine development has occurred primarily through observation and empiricism. In some cases, the emergence of new technologies allowed advances in vaccine development, and occasionally basic research discoveries have led to successful new vaccine approaches. The earliest observations that smallpox did not occur twice in the same individual led to the development of insuflation and variolization. Observing that a relatively innocuous cowpox infection seemed to protect against smallpox led Jenner to vaccinate. When Pasteur observed that an aged bacterial culture did not cause disease in chickens, and subsequently found that those chickens were protected from challenge with fresh cultures, an era of intentional modification and attenuation of microbes began that led to the introduction of many new vaccines. New technologies, such as cell culture, led to a series of new vaccines because viruses such as measles, mumps, rubella, and polio could be cultivated and produced in large quantities. The advent of molecular biology has led to the production of subunit proteins for successful hepatitis B and HPV vaccines and the technical ability to produce reassortant and recombinant viruses. Modern immunology, driven largely by the response to the HIV/acquired immunodeficiency syndrome (AIDS) crisis, has introduced new methods for measuring T-cell function that will help define the role of T cells in vaccine-induced immunity and guide the use of molecular adjuvants. Structural biology is providing an increasingly rapid way to view the atomic structures of viruses and their antigenic determinants bound to Abs and suggesting new approaches for vaccine design. The expanded capacity for nucleic acid sequencing has facilitated the discovery and surveillance of viral threats and has provided new insights to the biology of viruses and immune effectors. Technological advances in engineering and manufacturing have made vaccines safer and have created many new approaches for delivery that will have additional benefits on safety, stability, and ease of administration.

Vaccine development typically has required decades to accomplish and has never been a process that could occur in response to a crisis. However, a better awareness of the inevitability of new emerging infectious diseases and heightened concerns about bioterrorism have challenged traditional processes and compelled the consideration of new approaches. For example, the FDA has created the Two Animal Rule, which is a provision for vaccine licensure based on efficacy data in animal models combined with safety data in humans for diseases that are not conducive to efficacy trials.⁴¹⁵ A test case for the ability to develop vaccines rapidly for emerging infectious diseases occurred during the outbreak of the SARS CoV. This disease was recognized in the winter of 2003; the virus was identified in March 2003; a full-length sequence was obtained in April 2003; and vaccine development of whole inactivated, vector-based, DNA, and subunit vaccines began immediately.

Phase I clinical trials of the whole inactivated virus vaccine began in the summer of 2004, and DNA trials started in December 2004. Fortunately, by that time, the epidemic had been contained through classical public health approaches of surveillance and quarantine. In 2009, when the pandemic H1N1/A/California/2009 virus appeared, both commercially licensed approaches and some experimental vaccines were in clinical use or testing within 4 months. It is possible that in the future, platform technologies for classes of viruses will allow even more rapid development time lines. Just as toxoids and polysaccharide conjugates have been successful platform technologies for toxin-producing and encapsulated bacteria, respectively, patterns are emerging for vaccine approaches that have a high likelihood of success against some types of virus. For example, using reassortment to produce live attenuated vaccines for viruses with segmented genomes, or producing VLPs with the capsid proteins of nonenveloped and some enveloped viruses, appear to be viable platforms for those types of viruses. Although this chapter has focused on antiviral vaccines for human pathogens, much can be learned from the development of veterinary vaccines. The list of licensed veterinary antiviral vaccines that are shown in [e-Table 14.3](#) is provided to demonstrate the enormous variety of viruses to which vaccines have been developed, to demonstrate the types of approaches that have had some measure of success against various virus families, and to illustrate that the introduction of gene-based vaccine approaches into veterinary practice is anticipating the evolution of new human vaccines (see [e-Table 14.3](#)).

The goal for future vaccine development is to identify preventive strategies for selected pathogens that cause a large disease burden (e.g., HIV-1, RSV, dengue, and HSV) and have the potential for sporadic epidemics or intentional release and high disease severity (e.g., orthopoxviruses, filoviruses, flaviviruses), or emerging pathogens with the potential for causing widespread epidemics (e.g., chikungunya or H5N1 influenza), and at the same time develop platform technologies that can be deployed more rapidly when new virus diseases emerge (e.g., SARS CoV and West Nile virus). The 21st century promises higher capacity for protein production, structure-based Ag design, molecular adjuvants, and delivery devices to direct immune response patterns, a better understanding of the genetics of human immune response polymorphisms and repertoire, and more complete knowledge of immune effector mechanisms. In addition, the safety and efficacy of several classes of gene-based delivery vectors will be determined. These advances will hopefully provide the knowledge and infrastructure needed to develop vaccines for new emerging viruses and for difficult viruses that have eluded vaccine solutions and continue to impact human health.

ACKNOWLEDGMENTS

We acknowledge the extensive work done by Sandra Sitar, done on [e-Table 14.1](#) outlining the history of viral vaccine development. We are grateful to Robert Seder, Richard Schwartz, Rick King, Philip Johnson, and Steve Whitehead for their careful review of selected sections. We also thank our many colleagues who have contributed to our thoughts about viral vaccines, particularly David T. Karzon and Robert M. Chanock, who died since the last edition of this book.¹⁶⁰

Disclosures

Diagnostic virology continues to evolve rapidly. Viral testing is now essential for the care of a number of patient groups, including hospitalized patients with acute respiratory infections; transplant recipients and other immunocompromised patients; patients infected with human immunodeficiency virus (HIV), hepatitis C virus (HCV), and hepatitis B virus (HBV); and infants with possible congenital infection. Multiple test methods continue to be used, but molecular tests are emerging as the dominant technology. A variety of commercial molecular assays have been or are in the process of being approved or cleared as *in vitro* diagnostic tests by the Food and Drug Administration (FDA). This is an important development because it makes viral diagnostic testing available to more laboratories and it improves the standardization of diagnostic testing. The scope of diagnostic virology has broadened. General categories of viral diagnostic testing and the viruses included in those categories are shown in Table 15.1.

HISTORY OF DIAGNOSTIC VIROLOGY

Modern diagnostic virology dates to the first growth of human viruses in tissue culture reported by Weller and Enders in 1948.¹⁴⁹ This and other landmarks in the history of diagnostic virology are shown in Table 15.2.

SPECIMENS FOR VIRAL DIAGNOSIS

The likelihood of making a specific viral diagnosis depends largely on the quality of the specimen that is received in the laboratory. Important variables include the timing of the specimen in relation to the patient's illness, the type of specimen, the quality and amount of specimen material obtained, and the time and conditions of transport to the laboratory. Although this concept is so basic as to seem trivial, optimizing the variables listed requires knowledge on the part of the physician and attention to logistic considerations that can present substantial barriers to diagnosis.

For the diagnosis of acute viral infections, the best specimens are usually obtained from the site of disease. For example, in the patient with suspected viral meningitis, cerebrospinal fluid (CSF) is the best specimen. In infections involving skin or mucosal surfaces, specimens obtained from those surfaces are usually the only ones required. Viral titers are highest early in the course of an acute illness, so that specimens obtained within the first few days after onset are most likely to be positive.

Viral culture requires more attention to conditions of transport than specimens submitted for detection of viral antigens or nucleic acids, because the viability of the virus must be preserved. A number of clinically important viruses are labile and will not survive prolonged transport. General instructions for transporting specimens for viral culture are shown in Table 15.3. These conditions are usually also suitable for detection of viral antigens and nucleic acids, but consultation with the laboratory performing testing is advised.

For serologic diagnosis, an acute phase serum specimen should be obtained within the first few days of illness and a convalescent phase specimen 2 to 4 weeks later. If a virus-specific immunoglobulin M (IgM) assay is available, the acute phase specimen may be sufficient by itself. Immunoglobulins are stable in serum or plasma. Proper handling of specimens for serologic diagnosis begins with separation of serum or plasma. If testing is performed within several days, the serum or plasma can be stored at 4°C. If a longer delay is involved, the specimen should be frozen at –20°C or –70°C. For certain viral infections, serologic tests can also be performed on saliva or urine.

TABLE 15.1 Categories of Testing Performed in Diagnostic Virology

Category of testing	Specific viruses	Methodology
Respiratory viruses	Influenza A and B, RSV, PIV 1–4, hMPV, rhinoviruses, enteroviruses, coronaviruses, adenoviruses	Rapid antigen tests (influenza A and B, RSV), fluorescent antibody staining (influenza A and B, RSV, PIV 1–3, adenoviruses, hMPV), culture, multiplex NAAT
Gastrointestinal viruses	Rotavirus, norovirus, adenovirus, astrovirus	Rapid antigen tests (rotavirus, norovirus, adenovirus), NAAT
Mucocutaneous viruses	HSV, VZV, HPV	Fluorescent antibody staining (HSV and VZV), culture (HSV and VZV), NAAT
Central nervous system viruses	HSV, VZV, CMV, EBV, HHV-6, JCV, enteroviruses, parechoviruses, West Nile virus, other arboviruses	NAAT, serology (West Nile and other arboviruses)
Opportunistic agents	CMV, EBV, BKV, HHV-6, adenoviruses	NAAT, antigen detection (CMV pp65 assay), cytology (BKV)
Mononucleosis syndrome in nonimmunocompromised individuals	EBV, CMV, HIV	Serology, NAAT
HIV, HCV, HBV viral loads	HIV, HCV, HBV	NAAT
Viral genotyping	HCV, HBV, HPV	Nucleotide sequencing, reverse hybridization, NAAT (Cleavase reaction for HPV)
HIV, HCV, HBV diagnosis	HIV, HCV, HBV	Serology, NAAT
Systemic infections of childhood	Parvovirus B19, measles virus, rubella virus, mumps virus	NAAT, serology
Tropical and emerging infections	Dengue and other flaviviruses; chikungunya and other alphaviruses; hemorrhagic fever viruses including arenaviruses, bunyaviruses, and filoviruses; Hendra and Nipah viruses	Serology, culture, NAAT (hemorrhagic fever testing is done in BSL-4 laboratories)
Unknown virus	Any	Culture, microarray, nucleotide sequencing

BKV, BK virus; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV-6, human herpesvirus 6; HIV, human immunodeficiency virus; hMPV, human metapneumovirus; HPV, human papillomavirus; HSV, herpes simplex virus; JCV, JC virus; NAAT, nucleic acid amplification testing; PIV, parainfluenza virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

TABLE 15.2 Landmarks in the History of Diagnostic Virology

Year	Landmark
1892	Intranuclear and intracytoplasmic inclusions noted at the base of smallpox lesions ⁴⁷
1898	Discovery by Loeffler and Frosch that foot-and-mouth disease of cattle is caused by a filterable agent, referred to as a virus
1929	Complement fixation method described for detection of antibodies to smallpox, vaccinia, and varicella-zoster viruses ⁶
1948	First growth of pathogenic human viruses in tissue culture ¹⁴⁹
1956	Detection of influenza virus in respiratory secretions using fluorescent antibody staining ^{36,80}
1975	Development of monoclonal antibodies as diagnostic reagents ⁶⁸
1985	Discovery of PCR ¹¹⁸
1992	Development of real-time PCR ⁵³
2002	Beginning of systematic approaches to virus discovery ^{45,91,148}
2007	Description of multiplex PCR for respiratory viruses ⁸⁵

PCR, polymerase chain reaction.

SIGNIFICANCE OF VIRAL DETECTION

As in other areas of microbiology, the detection of a virus in a clinical sample is not proof in and of itself that the detected virus is the cause of the patient's illness. This problem regarding viral causality is exacerbated by polymerase chain reaction (PCR) and other very sensitive detection methods that may reveal very low-level persistent infection or even latent infection, unrelated to the patient's current illness. A determination of whether a causal relationship exists requires consideration of several factors. Two of the most important are (a) the nature of the virus–host interaction and (b) whether the virus is known to cause the disease manifestations that the patient is experiencing. If the virus detected is one known to be associated with persistent or latent infection, its detection may require other supportive evidence before it can be accepted as causal of the patient's current illness. For example, detection of the presence of virus-specific IgM antibodies or of seroconversion, in addition to the presence of the virus, favors acute infection, which, in turn, favors a causal relationship. An alternative approach using molecular methods may be to detect a specific viral RNA that encodes a structural or other protein that is expressed only in active infection. Obviously, detection of a virus known to cause the disease that the patient has is much more likely to be causal than detection of a virus not

TABLE 15.3 Instructions For Obtaining and Transporting Specimens for Viral Testing^a

Specimen	Instructions ^b
Blood	Volume requirement varies according to the specific test required. Molecular methods generally require lower blood volumes than does culture. The appropriate tube is determined by the test to be performed, the blood component on which the test is performed (whole blood, leukocytes, plasma, or serum), and the preference of the laboratory. Whole blood, leukocytes, and plasma require collection into a tube containing an anticoagulant. The most commonly used anticoagulants are ethylenediaminetetraacetic acid (EDTA) (purple top tube), heparin (green top tube), and acid-citrate-dextrose (yellow top tube). Note: Heparin is inhibitory for some polymerase chain reaction (PCR) procedures, especially those performed on plasma. Some nonculture tests performed on blood may have specific collection tube requirements that can be determined through communication with the laboratory. Most serologic procedures are performed on serum, although some tests can also be performed on plasma. Serum specimens require collection into a tube that does not contain an anticoagulant (red top tube or gold top serum separator tubes). Blood specimens do not have to be placed on ice if transport requires less than 1 day. Note: Prolonged transport can severely compromise the ability to recover cytomegalovirus (CMV) in culture from blood specimens. ¹¹⁴
Swab	Swabs with Dacron or rayon tips are preferred. If available, swabs designed specifically for collection of viral specimens should be used. Recently, flocked swabs have been shown to be superior to standard swabs. ^{1,90} Swabs can also be placed in viral transport media. In this case, the shaft of the swab may have to be cut to allow the top of the transport vial to be securely closed. The swab or tube of transport media should be placed on ice if transport will require more than 1 hour.
Fluid	Place in a sterile container.
Tissue	Place in a sterile container with a small amount of viral transport media or sterile saline or phosphate-buffered saline to maintain moisture.
Stool	Obtain at least 4 g of stool. Place in a clean or sterile container.

^aSpecimens other than blood should be transported on ice if more than 1 hour is required for arrival in the laboratory. If a delay of more than 24 hours is anticipated, specimens should be frozen at -70°C and transported on dry ice. Note: Some viruses such as respiratory syncytial virus (RSV) and varicella-zoster virus (VZV) are unlikely to retain viability with freezing. Specimens should not be frozen at -20°C .

^bCommercial tests may have specific recommendations for collection and transport. These should always be followed to ensure proper assay performance.

known to be associated with that disease. This applies particularly to viruses such as human herpesvirus type 6 (HHV-6) and type 7 (HHV-7), human polyomaviruses such as JC virus, non-high-risk types of human papillomavirus (HPV), and even respiratory or gastrointestinal viruses such as rhinovirus or adenoviruses that may be present in patients who are not ill.

METHODS USED IN DIAGNOSTIC VIROLOGY

Viral Culture

For approximately 50 years, viral culture was the signature method of diagnostic virology laboratories, and it was the method that led to the establishment of virology laboratories as distinct entities apart from other areas of the clinical laboratory. With the advent of immunological and especially of molecular methods, which are more rapid than viral culture and potentially detect a broader range of viruses, cell culture is playing a diminishing role. For this reason, the treatment of cell culture in this chapter will be brief, and the interested reader is referred to other sources.^{77,78,125,144}

By their very nature, viruses require living systems for propagation. In the past, inoculation of animals such as suckling mice or of embryonated eggs was used to grow viruses. These methods were largely supplanted by cell culture in the diagnostic laboratory. To grow viruses in cell culture, a clinical sample is prepared and then inoculated onto one or more cell culture types. Typically several cell culture types are inoculated, because no one type supports the growth of all clinically

relevant viruses. Cell culture types that are commonly used are shown in Table 15.4. After inoculation, viral growth is detected in one of several ways. Traditionally, the principal method was the appearance of cytopathic effect, which refers to morphologic changes observable by microscopy that occur in virally infected cells (Fig. 15.1). Alternatively, hemadsorption, which refers to the surface binding of erythrocytes by virally infected cells, was used for the detection of influenza, parainfluenza, and mumps viruses. Interference, used to detect rubella virus, refers to the phenomenon that cells infected with certain viruses such as rubella virus become resistant to infection with other viruses that would readily infect the cells if they were uninfected by the first virus. Confirmation of virus growth, suspected based on one of the indicators described previously, can be achieved by immunofluorescence using specific antiviral antibodies. When cytopathic effect is present but immunological stains are negative, electron microscopy of cell culture material can be used to examine the culture. More recently, molecular methods such as VIDISCA (virus discovery based on complementary DNA [cDNA]-amplified fragment length polymorphism) have been used in this situation to detect new viruses growing in cell culture.^{107,132}

Presently, most viral culture done in diagnostic virology laboratories is performed using centrifugation cultures, also often referred to as shell-vial cultures (Fig. 15.2). The shell-vial culture method was originally developed for cytomegalovirus (CMV)^{42,46} but has subsequently been applied to many other viruses. In this method, viral entry is enhanced by a low-speed centrifugation after inoculation of the clinical sample onto the cell culture, which may be grown on a cover

TABLE 15.4 Cell Culture Types Used to Detect Medically Important Viruses

Primary	Monkey kidney Rabbit kidney Human embryonic kidney	Influenza viruses, parainfluenza viruses, enteroviruses Herpes simplex virus Adenovirus, enteroviruses
Diploid	Fibroblasts (e.g., MRC-5, WI-38)	CMV, VZV, HSV, rhinovirus, enteroviruses (some), adenovirus, RSV
Continuous	HEp-2 A549 MDCK LLC-MK2 Rhabdosarcoma (RD) Buffalo green monkey	HSV, adenovirus, enteroviruses (some), enteroviruses (some) HSV, adenovirus, enteroviruses Influenza viruses Parainfluenza viruses, hMPV Echoviruses Coxsackieviruses

CMV, cytomegalovirus; hMPV, human metapneumovirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

slip within a 1-dram vial referred to as a shell vial, but can also be grown within other devices such as 24-well plates that can be conveniently centrifuged. Viral growth is detected by immunofluorescence, typically at 16 and 40 hours after inoculation, allowing detection of viruses much sooner than could be accomplished using conventional tube cultures. It is now possible to purchase cell cultures for centrifugation cultures in which more than one type of cell is present. For example, a commercial system called R-Mix (Diagnostic Hybrids, Inc., Athens, Ohio) combines human adenocarcinoma (A549) and mink lung cell lines for growth of respiratory viruses. After incubation, the R-Mix cells are stained with a mixture of monoclonal antibodies specific for seven respiratory viruses. Similar mixed cell culture systems also exist to detect herpes simplex

virus (HSV) and varicella-zoster virus (VZV) and to detect enteroviruses.

Genetically Engineered Cell Lines

Techniques of genetic engineering have been used to modify cell lines either to make them susceptible to viruses to which they are not otherwise susceptible or to create novel means of detecting virus growth. An example is a cell line developed by Stabell and Olivo¹²⁶ for the detection of HSV. This cell line, shown in Figure 15.3, consists of baby hamster kidney (BHK) cells that have been transfected with the β -galactosidase gene from *Escherichia coli* under the control of a promoter from the herpes simplex gene *UL39*. The promoter is activated by exposure to HSV proteins ICP0 and VP16. Exposure of the cells to

FIGURE 15.1. Cytopathic effect caused by viruses growing in cell culture. Herpes simplex virus growing in primary rabbit kidney cells (A); uninfected primary rabbit kidney cells (D). Respiratory syncytial virus growing in HEp-2 cells (C); uninfected HEp-2 cells (F).

FIGURE 15.2. Shell-vial assay for cytomegalovirus. (From Shuster EA, Beneke JS, Tegtmeier GE, et al. Monoclonal antibody for rapid laboratory detection of cytomegalovirus infections: characterization and diagnostic application. *Mayo Clin Proc* 1985;60:577–585, with permission.)

a specimen containing HSV specifically activates the promoter, causing production of β -galactosidase, which can be detected by a simple histochemical stain of the culture, performed 16 to 24 hours after inoculation. A commercial version of this system, called ELVIS HSV (Diagnostic Hybrids, San Diego, CA), has been shown to have sensitivity comparable to conventional viral culture for detection of HSV in clinical specimens.¹²⁷ The system has also been adapted to the performance of HSV

antiviral drug susceptibility assays.¹³³ Another example is the creation of a line of buffalo green monkey (BGM) cells that have been modified to express human decay-accelerating factor, which is a receptor for some enterovirus serotypes.⁵⁶ Addition of this molecule increases the ability of unaltered BGM cells to grow enteroviruses. These cells are combined with A549 cells in a commercial product called Super E-Mix (Diagnostic Hybrids).

Electron Microscopy

Viral infections are rarely diagnosed using electron microscopy for the direct visualization of viral particles in specimens. Advantages include speed, lack of requirement for viral viability, and the potential to visualize many different kinds of viral particles. Disadvantages include the cost and complexity of maintaining an electron microscopy, the need for a skilled operator, and limited sensitivity related to the relatively high concentration of viral particles (10^5 to 10^6 /L) that is required for visualization.⁸⁹ Historically, electron microscopy was used for the evaluation of stool specimens from patients with suspected viral gastroenteritis. Viruses such as rotavirus, astrovirus, and adenovirus could be identified based on their characteristic morphology, but this has been replaced by rapid immunoassays and PCR assays. Electron microscopy can also be used to detect and classify viral particles in fixed tissue obtained by biopsy or at autopsy. Screening of tissue samples by electron microscopy is not useful because of the small area of tissue that can be examined. Thus, electron microscopy is best employed when it is directed by evidence of viral infection detected by routine histology.

FIGURE 15.3. ELVIS herpes simplex virus (HSV), a genetically engineered cell line for the detection of HSV clinical samples. ELVIS cells are baby hamster kidney (BHK) cells that contain a β -galactosidase gene under the control of the HSV promoter UL39. If HSV is present in the specimen, viral particles enter the cells and the HSV proteins ICP0 and VP16 activate the UL39 promoter, leading to synthesis of β -galactosidase. The presence of β -galactosidase is detected by adding X-gal, a substrate for the enzyme. The activity of β -galactosidase on X-gal results in blue staining of ELVIS cells, visible microscopically.

Light Microscopy

Although viral particles, with the exception of poxviruses, cannot be directly visualized by light microscopy, indirect evidence of viral infection can be detected. The most characteristic signs of viral infection are inclusion bodies (composed of masses of virions), multinucleated cells, and syncytial cells. These findings may be present in cytologic specimens or in tissue examined after histologic staining. Viral inclusions can be found in the nucleus or the cytoplasm of infected cells. The location is characteristic of the responsible virus. The location of viral inclusions is summarized in Table 15.5. Microscopy for detection of the effects of viral infections in clinical specimens is generally carried out in surgical pathology rather than diagnostic virology laboratories.

Cytology and Histology

Cytologic examination for evidence of viral infection can be performed on smears prepared by applying a specimen directly to a microscope slide, on slides prepared by cytocentrifugation of fluids (e.g., bronchoalveolar lavage fluid), and on touch preparations prepared from pieces of unfixed tissue. Viruses that can produce cytologic evidence of infection in respiratory specimens include HSV, CMV, adenoviruses, polyomaviruses, and measles virus (Warthin-Finkeldey cells). Cytologic examination is usually not a sensitive method for detection but provides strong evidence for tissue involvement. Examples of cytologic findings suggestive of viral infection are shown in Figure 15.4. The Tzanck smear is a method sometimes used to detect cytologic evidence of HSV or VZV infection. It is rarely used in diagnostic virology laboratories because techniques such as fluorescent antibody staining and PCR are more sensitive and specific. The Papanicolaou stain (Pap smear) is used to detect evidence of HPV infection in cells obtained from the uterine cervix. HPV infection produces characteristic changes in keratinocytes, including a condensed nucleus with a prominent perinuclear clear zone referred to as *koilocytosis*. More specific evidence of the presence of HPV can be provided by histochemical stains or molecular techniques. Urine cytology may reveal intranuclear inclusions indicative of infection with either CMV or the polyomaviruses, JC and BK. Culture or PCR for CMV and PCR for polyomaviruses, however, are more sensitive and specific techniques. Cytology does not distinguish between JC and BK viruses.

FIGURE 15.4. Cytologic findings suggestive of viral infection.

A: Cervical smear showing multinucleated cells and the Cowdry type A intranuclear inclusions of herpes simplex infection. **B:** Papanicolaou smear showing binucleate squamous epithelial cells with distinct perinuclear halos. These characteristics, described as *koilocytosis*, are the cellular features associated with human papillomavirus infection. **C:** Urinary epithelial cell containing an enlarged nucleus with smudgy chromatin and a small pale *glassy* intranuclear inclusion indicative of polyomavirus infection. **D:** Cell from bronchoalveolar lavage with a large intranuclear inclusion with a perinuclear clear space (owl's eye cell) indicative of cytomegalovirus infection. (Photographs provided by Dr. Leslie Boucher, Department of Pathology, Washington University, St. Louis, Missouri.)

Histologic examination of stained tissue can provide unique information about the role of viral infection in producing tissue inflammation and injury and can be very useful in distinguishing between asymptomatic viral shedding and clinically significant infection. This is particularly useful for CMV infections in which prolonged viral shedding can occur without producing disease. For example, the presence of cytomegalic inclusion cells in tissue obtained by biopsy or at autopsy is often considered to be the gold standard for diagnosing clinically significant CMV infection localized in a specific organ.

Antigen Detection

The detection of viral antigens directly in clinical specimens is widely used to obtain rapid evidence of viral infection. The lack of requirement for virus viability is an important advantage. For some viruses, especially respiratory syncytial virus (RSV) and CMV, the sensitivity of antigen detection may exceed that of viral culture.^{111,135} Antigen detection methods can be applied when the following conditions are met: (a) viral antigen is expressed and is present in an accessible specimen, (b) an appropriate antibody (usually but not necessarily monoclonal) is available, (c) antigenic variability does not preclude recognition by immunologic reagents of different strains of the target virus, and (d) the antigen being detected is sufficiently stable that it does not degrade during transport and processing of the specimen. Methods used for viral antigen detection include fluorescent antibody (FA) staining, immunoperoxidase staining, and enzyme immunoassay. The latter can be subdivided

TABLE 15.6 Viral Antigen Detection: Specimens Used and Viruses Detected

Specimen	Viruses detected
Respiratory (nasopharyngeal swab or aspirate, nasopharyngeal wash, tracheal aspirate, bronchoalveolar lavage)	Respiratory syncytial Influenza A, B Parainfluenza 1–3 Adenovirus Human metapneumovirus Measles
Skin or mucous membrane scraping	Herpes simplex Varicella-zoster
Conjunctival or corneal scraping	Herpes simplex Adenovirus
Stool	Rotavirus Adenovirus (enteric serotypes) Norovirus
Blood	Cytomegalovirus (pp65) Hepatitis B (surface antigen) Human immunodeficiency (p24)

into solid phase and lateral flow immunochromatographic assays. The viruses for which antigen detection assays are in widespread use are shown in Table 15.6.

Antigen detection can also be used to detect viral antigens in fixed tissue (immunohistochemistry [IHC]). This method can document the specific viral etiology of a nonspecific finding such as an inclusion body that could be produced by several different viruses. In some cases, IHC also enhances the sensitivity of detection of viruses in tissue compared to standard light microscopy without immunostaining. Immunoperoxidase staining is the most common technique used for viral antigen detection in fixed tissue. IHC can often be performed on formalin-fixed tissue, but for some antigen–antibody combinations, sensitivity is better on fresh frozen tissue.

Fluorescent Antibody Staining

Fluorescent antibody staining is widely used to detect cell-associated viral antigens. In the direct format, a fluorescent label, usually fluorescein isothiocyanate (FITC), is conjugated directly to the antibody that recognizes the viral antigen. In the indirect format, the antiviral antibody is unlabeled and is detected by a second antibody that recognizes immunoglobulins from the animal species of origin of the antiviral antibody. The second antibody carries the fluorescent label. After staining, the specimen is viewed with epi-illumination using ultraviolet (UV) light of the wavelength needed to excite the fluorescent label. The direct method is simpler to use but requires conjugation of each antiviral antibody with the fluorescent label. The indirect method is slightly more sensitive and more versatile, because only the anti-immunoglobulin antibody has to be conjugated with the fluorescent label.

The main applications of FA staining have been to detect respiratory, ocular, cutaneous, and bloodstream pathogens. Many different respiratory specimens can be used, including nasopharyngeal swabs or aspirates, nasal washes, tracheal aspirates, and bronchoalveolar lavage fluid. In each case, the specimen is processed in the laboratory to prepare a pellet of cells, which is spotted onto one or more microscope slides. The cells

are air dried, fixed in acetone, and stained with monoclonal antibodies to one or more viruses. For ocular infections, material is scraped from the conjunctiva or cornea, placed on microscope slides, and processed as described for respiratory specimens. Staining is usually directed at detection of HSV and adenovirus antigens. For cutaneous infections, the lesion is scraped with a scalpel blade or swab, and cellular material obtained is placed directly on one or more microscope slides. Alternatively, the base of the lesion can be rubbed vigorously with a swab and the swab submitted to the laboratory, where cellular material is washed from the swab and spotted onto a microscope slide. The use of cyto centrifugation to prepare the slides has been shown to improve the results.⁷⁵ Staining is directed at detection of HSV and VZV. In the CMV pp65 antigenemia assay, peripheral blood leukocytes are separated from anticoagulated blood; spotted onto a microscope slide, usually by cyto centrifugation; and stained using a monoclonal antibody specific for the CMV pp65 antigen. The major limitation of FA staining is having an adequate number of cells in the specimen. Immunoperoxidase (IP) staining is similar to FA staining, except that horseradish peroxidase is used in place of a fluorescent label, making it possible to view the stain using light microscopy rather than requiring fluorescence microscopy. It is more often used to detect viral antigens in fixed tissue rather than directly in patient samples.

Enzyme Immunoassay

Enzyme immunoassay (EIA) is a versatile and widely used method that can be applied to the detection of antigens, regardless of whether they are cell associated or in fluid phase. Because intact cells in the specimen are not required, specimen integrity is less important than for FA or IP staining. This may be advantageous when specimen transport time is prolonged. A common assay format for antigen detection is the double antibody sandwich technique, shown in Figure 15.5. In this assay, a *capture* antibody specific for the viral antigen being sought is bound to a reaction surface, for example, the wells of a plastic microtiter tray or the surface of a plastic bead. When the specimen is added, viral antigen present in the specimen binds to the capture antibody. Bound antigen is detected using a different antiviral antibody, the *detector* antibody. The detector antibody can be labeled with an enzyme or can be detected by

FIGURE 15.5. Enzyme immunoassay (EIA) for antigen detection. **A:** Direct. **B:** Indirect.

FIGURE 15.6. Lateral flow immunochromatographic assay. The sample is applied to the sample pad. The sample flows across the unit from left to right, drawn by the absorbent pad. Located in the label pad are one or more antibodies, each of which is conjugated to a label such as gold particles. These antibodies bind to antigen present in the sample as it moves across, forming complexes of antigen with conjugated antibody. If present, these complexes are then captured by second antibodies, located in lines in the capture membrane zone. When complexes are captured, the presence of the conjugated label causes the line to become visible. In the figure, antibodies against the target antigen are indicated by “A,” and antibodies against a control antigen are indicated by “C.” Presence of a colored line corresponding to A is a positive test. Presence of a line corresponding to C in the absence of a line corresponding to A indicates a negative test. Absence of both lines indicates that the test is not valid. (Figure provided by John Tamerius, Quidel Inc.)

the addition of an enzyme-labeled third antibody with specificity for immunoglobulin of the species from which the second antibody was derived. The addition of an enzyme substrate produces a color change or light emission if the enzyme is present. Thus, color change or light emission indicates that viral antigen was present in the specimen being tested. Advantages of EIA include applicability to diverse specimens and potential for automation. Laboratory instruments are now available that can perform EIA to detect either antigens or antibodies. Viruses for which antigen EIA have been widely used are RSV, influenza, rotavirus, enteric adenoviruses, HSV, HBV, and HIV.

Membrane Immunoassay

The lateral flow immunochromatographic assay is a variant of EIA that was first used in home pregnancy tests. A schematic diagram of a lateral flow unit is shown in Figure 15.6. In these tests, a sample is applied directly to a membrane and is drawn across the membrane by capillary action. Antigens in the sample react first with an antibody with specificity for the antigen being detected. This antibody is conjugated to a detector label such as gold particles or fluorescein. If binding occurs, the antigen–antibody complexes sweep across the membrane until they are captured by a second antibody that is bound to the membrane. When the labeled antigen–antibody complexes are captured, a line becomes visible because of the concentration of the label into a limited physical space. Most assays also include a positive control. These assays can be configured as dipsticks or as self-contained cassettes. Standard lateral flow immunochromatographic assays do not require an instrument and are convenient for testing single samples, with results available in 5 to 20 minutes. Multiple commercial versions are now available, mainly for

detection of influenza, RSV, and rotavirus. Some of the tests are sufficiently simple to perform that they have been assigned *waived* status under the Clinical Laboratory Improvement Amendments (CLIA), meaning that they can be performed by individuals without specific training who can be working within or outside of a certified clinical laboratory. Unfortunately, sensitivity of these tests has generally been less than that for fluorescent antibody staining, culture, or PCR. This problem was especially true for commercial influenza lateral flow tests in detecting the 2009 H1N1 pandemic.¹⁰⁶ A recent test developed by 3M (3M Rapid Detection RSV or Influenza tests, 3M, St. Paul, MN) achieves increased sensitivity by using fluorescent beads conjugated to a detector antibody and reading the captured antigen–antibody complexes in a fluorescence reader.⁴¹

Nucleic Acid Detection

Diagnostic virology has been revolutionized by the application of nucleic acid detection techniques, which detect specific DNA or RNA sequences, and can be applied to the detection of virtually any virus. Depending on the target sequence, the assays can be specific for a single virus species or for a group of related viruses. The latter characteristic is particularly advantageous, because it allows nucleic acid detection techniques to be applied to groups of viruses (e.g., the enteroviruses) for which antigenic diversity has precluded successful application of antigen detection techniques. For example, enteroviruses, for which a rapid nonmolecular detection method had not been available, can be detected using reverse-transcription PCR assays that amplify a highly conserved sequence in the 5′ nontranslated region of the genome.^{14,115} An overview of applications of nucleic acid testing in diagnostic virology is shown in Table 15.7.

TABLE 15.7 Nucleic Acid Detection for Viral Diagnosis

Target	Specimen(s)	Application(s)
HIV (DNA)	Leukocytes from infant born to HIV-infected mother	Diagnosis of perinatal infection
HIV (quantitative RNA)	Plasma	Viral load (prognosis, response to treatment)
HIV (qualitative RNA)	Plasma	Confirmation of diagnosis
HSV	CSF, ocular fluid, swabs from mucocutaneous lesions	Diagnosis of encephalitis, meningitis, retinitis, mucocutaneous lesions
VZV	CSF, ocular fluid, swabs from mucocutaneous lesions	Diagnosis of encephalitis, meningitis, retinitis, mucocutaneous lesions
CMV	Blood (whole blood, leukocytes, or plasma), CSF, ocular fluid, amniotic fluid	Diagnosis of systemic infection after organ transplantation, encephalitis, radiculomyelitis, retinitis, congenital infection. Quantitative assay performed on blood can be used to assess severity of infection and monitor response to therapy.
EBV	CSF, blood (whole blood, leukocytes, or plasma)	Primary central nervous system lymphoma in AIDS, other EBV infection of the central nervous system, posttransplant lymphoproliferative disorder. Quantitative assay performed on blood can be used to assess the risk of PTLD and the response to therapeutic interventions.
HHV-6, -7	Blood, CSF	Diagnosis of systemic infection and of encephalitis
HHV-8 (Kaposi sarcoma virus)	Blood, pleural or pericardial fluid	Diagnosis of body cavity lymphoma
Adenovirus	Blood, respiratory secretions	Diagnosis and monitoring of disseminated infection in immunocompromised hosts, diagnosis of respiratory tract infection
Parvovirus B19	Serum, amniotic fluid	Diagnosis of acute or chronic parvovirus B19 infection, aplastic crisis, congenital infection
BK virus	Urine, plasma	Assessment of risk of transplant nephropathy in renal transplant recipients and of hemorrhagic cystitis in hematopoietic stem cell transplant recipients
Human papillomavirus	Genital secretions	Detection of viral types associated with cervical carcinoma
Enteroviruses	CSF, blood (whole blood, serum, or plasma)	Diagnosis of meningitis, encephalitis, or systemic infection
Hepatitis C	Plasma	Diagnosis of infection. Quantitative assay is used to assess response to therapy.
Hepatitis B	Serum	Diagnosis of infection when serologic studies are ambiguous. Recognition of virologically active infection. Quantitative assay is used to assess response to therapy and recognize emergence of drug resistance.
Rabies	Saliva, CSF	Diagnosis of rabies
Respiratory viruses	Respiratory samples	Enhanced sensitivity, including detection of noncultivable agents
Gastrointestinal viruses	Feces	Enhanced sensitivity, including detection of noncultivable agents
West Nile and other flavivirus infections	CSF, blood	Rapid diagnosis of CNS infection, especially in immunocompromised hosts, screening of blood units for presymptomatic infection
Dengue	Plasma	Diagnosis of early infection, genotyping
Arenaviruses	Serum or whole blood	Diagnosis of acute infection
Filoviruses	Serum or whole blood	Diagnosis of acute infection
Nipah and Hendra viruses	CSF, throat swabs, urine	Diagnosis of acute infection
Vaccinia and other pox virus infections	Lesion	Diagnosis of acute infection

CMV, cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; HHV, human herpesvirus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; PTLD, posttransplant lymphoproliferative disorder.

The earliest attempts at nucleic acid–based diagnosis involved direct hybridization of nucleic acid probes to viral nucleic acids present in clinical specimens. Direct hybridization was never widely adopted because it lacked adequate sensitivity, requiring the presence of 10^4 to 10^5 copies of the target nucleic acid. The development of PCR¹¹⁸ and other nucleic

acid amplification techniques overcame that sensitivity barrier and has led to the development of nucleic acid–based diagnostic tests for many viruses. Nucleic acid amplification tests (NAATs) were originally directed at viruses that were difficult or impossible to cultivate, viruses that grew very slowly in culture, and viruses for which antigen detection could not be applied

because of antigenic diversity or because the level of viral antigen in clinical specimens was too low to permit successful detection. NAATs were also very advantageous for specimens such as CSF or ocular fluid for which sample volume could be limiting. Still another advantage of nucleic acid detection as a diagnostic method is the stability of DNA as an analyte, so that detection of viral nucleic acids can be done even when conditions of transport lead to loss of virus viability. Currently NAATs are being applied to all viruses that are of interest in diagnostic virology.

Nucleic Acid Amplification Assays

TARGET AMPLIFICATION

Polymerase Chain Reaction. PCR, which is the prototype of target amplification assays, employs short oligonucleotide primers and a thermostable DNA polymerase such as *Taq* polymerase to amplify a segment of target DNA that is typically 100 to 1,000 base pairs (bp) in length. Classic PCR includes repetitive cycles, each consisting of denaturation, primer annealing, and extension steps that take place at different temperatures. Progression through the steps of the cycle is controlled by a thermal cycler that controls the temperature of the reaction. After PCR amplification, the PCR product (also known as the *amplicon*) is detected by gel electrophoresis or by one of several probe-hybridization techniques (e.g., Southern blotting). The analytic sensitivity of PCR can be as low as 1 to 10 copies of target DNA. Because of its simplicity and broad applicability, PCR remains the most widely used NAAT.

Currently, most PCR in diagnostic virology laboratories is carried out using real-time PCR in which reaction products are detected as they are synthesized.^{40,52} Numerous specialized instruments for running real-time PCR are now commercially available, including the LightCycler (Roche Diagnostics, Indianapolis, IN), the SmartCycler (Cepheid, Sunnyvale, CA), the ABI TaqMan 7000 series (Applied Biosystems, Foster City, CA), the Rotor Gene (Qiagen, San Diego CA), and many others. Compared with conventional PCR, real-time PCR has several important advantages. Because the accumulation of PCR product is monitored in the reaction tube, no separate detection method (e.g., gel electrophoresis) is required, thus shortening the effective assay time markedly and decreasing the risk of contamination of the laboratory environment by the amplified PCR product. The time from setting up the assay to completion can be less than 1 hour. The use of multiple fluorescent dyes with different emission wavelengths makes it possible to perform multiplex reactions with simultaneous amplification of more than one product. Of great importance, quantification of PCR targets is readily achieved because the generated fluorescence is proportional to the amount of PCR product.

Detection of PCR products in real-time PCR has generally used one of three methods, although other detection methods have also been introduced more recently. The simplest system uses the DNA binding dye SYBR Green, which emits fluorescence when it is bound to double-stranded DNA (dsDNA). When SYBR Green is included in a PCR reaction, the intensity of fluorescence is proportional to the amount of PCR product. Because SYBR Green binds nonspecifically to any dsDNA, signal is generated by undesired amplification products such as primer dimers, as well as by intended amplicons. Discrimination between different amplification products can be achieved through the use of dissociation curves, referred to as *melting*

point analysis. Melting point analysis is performed after completion of the amplification reaction by recording fluorescence as the temperature of the reaction mix is gradually increased. When the dissociation temperature (melting point) of the dsDNA reaction product is reached, SYBR Green is released and fluorescence decreases. The melting point is affected by both length and sequence of the PCR product, and thus is precisely defined for a specific PCR product. Unintended amplification products will usually have different melting points, allowing easy discrimination from the intended PCR product.

The other two detection systems are based on the use of oligonucleotide probes that are labeled with fluorescent dyes that interact with one another according to principles of fluorescence resonance energy transfer (FRET). The hybridization probe assay format requires two oligonucleotide probes that are homologous to adjacent portions of one of the strands of the amplified DNA. The probes are chosen so that the 5' end of one probe is within a few nucleotides of the 3' end of the other probe. These adjacent ends are each labeled with a fluorescent dye. The dye on the 3' end is termed the *donor dye* and the dye on the 5' end is termed the *acceptor dye*. The required property of these dyes is that when they are in close proximity (within a distance of several nucleotides), excitation of the donor dye leads to emission of light by the acceptor dye. When both probes bind to their target sequences, the two dyes are within the proximity required for excitation of the acceptor dye and fluorescence occurs. The fluorescence intensity is proportional to the amount of PCR product.

The other detection system based on interacting fluorescent dyes is the fluorogenic 5' exonuclease assay (also referred to as the *Taqman assay*). This assay uses a probe that is complementary to a segment of the intended PCR product located between the PCR primers. This probe is labeled with two fluorescent dyes, one called the *reporter* that is linked to the 5' end of the probe, and the other called the *quencher* that is linked to the 3' end. When they are in close proximity (i.e., bound to opposite ends of an oligonucleotide probe), the quencher prevents fluorescence by the reporter. During the extension step of PCR, the probe labeled with both dyes binds to the PCR product as it is being synthesized. During extension, the 5' exonuclease activity of *Taq* polymerase cleaves nucleotides from the 5' end of the bound probe, releasing the reporter dye away from the quencher, thus allowing it to emit light on excitation. As in the hybridization probe assay, the intensity of fluorescence is proportional to the amount of PCR product.

Because *Taq* polymerase uses only DNA as a template, the use of PCR to detect viral RNA sequences requires the inclusion of a reverse-transcription (RT) step before PCR (RT-PCR). The RT reaction can be performed using a devoted enzyme such as Moloney murine leukemia virus RT or avian myeloblastosis virus RT. Alternatively, heat-stable, multifunctional enzymes such as recombinant *Thermus thermophilus* DNA polymerase are now available that can carry out RT as well as DNA polymerase reactions. Special care must be used in specimen processing because of the susceptibility of RNA to digestion by ribonucleases that may be present in clinical samples. In addition to detecting virion RNA, RT-PCR can also be applied to the detection of viral messenger RNA. This may be particularly useful in the diagnosis of infection caused by viruses that have a latent phase in their life cycle. For these viruses, detection of viral DNA might not distinguish between

latent and productive infection, whereas detection of a messenger RNA (mRNA) expressed only in productive infection would be evidence of active viral infection.

RNA Amplification Assays. Several reactions have been developed that are directed at amplification of RNA. *Transcription-based amplification* (Fig. 15.7)^{48,73} uses three enzymes, RT, ribonuclease (RNase) H, and T7 RNA polymerase, to amplify a target RNA sequence, employing a series of reactions that mimic the retrovirus replication scheme. An advantage of transcription-based amplification assays is that they are isothermal and do not require complicated instrumentation. The assays begin with synthesis of a DNA strand that is complementary to the RNA target, using a primer that contains a T7 polymerase binding site at its 5' end. The resulting DNA–RNA hybrid is converted to dsDNA by the action of RNase H and a second primer that also contains a 5' T7 polymerase binding site. The dsDNA product then serves as a template for transcription driven by T7 RNA polymerase. The newly synthesized RNA transcripts serve as templates for additional cycles of the

reaction. Variants of transcription-based amplification include transcription-mediated amplification (TMA),³⁹ self-sustained sequence replication (3SR),⁴⁸ and nucleic acid sequence-based amplification (NASBA).²¹ Currently, NASBA assays for HIV, enteroviruses, and CMV pp67 have been approved by the FDA and are marketed by bioMérieux Inc. (Durham, NC) under the trade name NucliSENS. TMA is the basis for the Procleix assays for HIV, HCV, HBV, and West Nile virus marketed by Gen-Probe (San Diego, CA).

SIGNAL AMPLIFICATION

Examples of signal amplification assays include the branched-chain DNA (bDNA) assay,²² the hybrid capture assay,⁵¹ and the cleavase reaction.⁴⁹ The bDNA assay (Fig. 15.8) uses short, branched-chain oligonucleotides to capture the target nucleic acid sequence. Other branched-chain oligonucleotides link multiple molecules of detector enzyme to the captured target. A chemiluminescent substrate allows detection of the target, and measurement of the intensity of emitted light makes it possible to quantify the input target accurately. Because the target itself is not amplified, this reaction is less susceptible than PCR to carryover contamination. Currently, FDA-approved quantitative bDNA assays for HIV and HCV are marketed by Siemens USA (Deerfield, IL) under the trade name Versant.

The hybrid capture assay (Fig. 15.9) is a signal amplification assay that involves a liquid hybridization reaction between the denatured DNA target and RNA probes specific for the viral DNA sequence of interest. If the viral DNA is present, DNA–RNA hybrid molecules are formed and are captured and detected using an antibody specific for DNA–RNA hybrids. This assay can be used as either a qualitative or quantitative assay. Currently, FDA-approved or cleared hybrid capture assays for HPV and CMV are marketed by Qiagen (Valencia, CA).^{83,88}

The Invader assay (Fig. 15.10) is an isothermal reaction that makes use of (a) an enzyme referred to as Cleavase that functions as an FEN-1–encoded flap endonuclease,¹³⁶ plus (b) two short sequence-specific oligonucleotides termed the probe oligo and the Invader oligo. To initiate the reaction, the two oligos bind to the target DNA with a short region of overlap that is designed to occur at a targeted single nucleotide polymorphism (SNP). The overlap structure occurs only when exact base pairing occurs with the targeted SNP. The resulting structure forms a substrate for the Cleavase enzyme, which cleaves the primary probe oligo at the position of overlap, releasing the 5' portion, which is termed the *flap oligonucleotide*. The primary probe and the Invader oligos are present in large molar excess, resulting in generation of many cleaved flap oligos if the targeted SNP is present in the template. The flap oligo itself functions as an Invader oligo, binding to a hairpin region of a third oligo, termed a fluorescence resonance energy transfer (FRET) cassette because it contains a fluorophore and a quencher adjacent to one another at one end of the cassette. The sequence of the FRET oligo causes it to assume a hairpin configuration in which the quencher damps fluorescence from the fluorophore. Binding of the flap Invader generates another tertiary DNA structure that also functions as a substrate for the Cleavase enzyme. The resulting cleavage releases the fluorophore away from the quencher, which leads to the generation of a fluorescent signal. Reaction conditions that allow cycling of the probe oligo and the hairpin oligos cycle on and off their

FIGURE 15.7. Transcription-mediated assay, also called 3SR. The 3SR reaction depends on a continuous cycle of reverse transcription and transcription reactions to replicate an RNA target by means of complementary DNA (cDNA) intermediates. Steps 1–6 depict the synthesis of a double-stranded cDNA, which is a transcription template for T7 RNA polymerase. Complete cDNA synthesis is dependent on the digestion of the RNA in the intermediate RNA–DNA hybrid (step 4) by ribonuclease (RNase) H. Transcription-competent cDNAs yield antisense RNA copies of the original target (step 7, right). These transcripts are converted to cDNA containing double-stranded promoters on both ends in an inverted repeat orientation (steps 7–12). These cDNAs can yield either sense or antisense RNA, which can re-enter the cycle.

FIGURE 15.8. Branched-chain DNA assay as used for ultrasensitive detection of human immunodeficiency virus (HIV).

After liberation of viral nucleic acid from the clinical specimen by a lysis buffer, viral nucleic acid is hybridized with two sets of bifunctional oligonucleotide probes, each of which contains sequences complementary to the target. One set of probes also contains a generic sequence complementary to a capture probe that is bound to the surface of a microtiter tray and serves to bind the target to the solid surface. The other set of probes contains a sequence complementary to *preamplifier* molecules. Additional specificity is achieved because two of the target-specific probes must be juxtaposed in the correct orientation to stabilize the binding of the preamplifier molecule. Each preamplifier molecule binds numerous amplifier molecules, each of which binds many subsequently added alkaline phosphatase-labeled probes. A chemiluminescent substrate is added and generated light is read by a luminometer. The cascade effect results in amplification of the signal generated from initial binding of probes to the target and allows for detection and quantification of nucleic acid present in the specimen. (Courtesy of Bayer Diagnostics, Emeryville, California.)

respective targets result in the generation of 10^6 - to 10^7 -fold signal amplification per hour. Currently, FDA-approved tests using the Cleavase reaction to detect high-risk HPV types and to genotype HPV types 16 and 18 are marketed by Hologic (Bedford, MA) (formerly Third Wave Technologies) under the trade name Cervista.

The loop-mediated isothermal amplification (LAMP) (Fig. 15.11) is an amplification reaction that employs four primers and a strand-displacing DNA polymerase.⁹⁶ It was developed originally by Eiken Chemical Co. (Tokyo, Japan), and additional detailed diagrams of the assay can be viewed on the Eiken web page: <http://loopamp.eiken.co.jp/e/lamp/index.html>. The inner primers have sense and antisense sequences. When they initiate DNA synthesis, the result is a stem-loop structure, which itself serves as a target for additional amplification. The resulting reaction can produce 10^9 copies of target DNA or RNA in less than 1 hour under isothermal conditions. The reaction can be monitored by measuring turbidity, which results from the accumulation of magnesium pyrophosphate, a by-product of the reaction. Alternatively, the synthesis of dsDNA can be measured using an agent such as SYBR Green, which generates fluorescence when it intercalates between the strands of dsDNA. The reaction has high specificity by virtue

of the inclusion of multiple primer sets. The isothermal nature of the reaction, which obviates the requirement for a thermal cycler, makes LAMP attractive for use as a point-of-care test or for use in the developing world.

CONTAMINATION

A general concern regarding highly sensitive nucleic acid amplification assays is the occurrence of false-positive findings resulting from contamination of the reaction with exogenous nucleic acids. The source of contaminating nucleic acids can be either amplified products from previous reactions or viral nucleic acids present in a different specimen, especially one containing a high level of the intended target. Prevention of contamination requires fastidious attention to procedural detail within the laboratory. A number of specific preventive techniques are widely used to prevent carryover contamination after PCR, including the use of positive displacement pipettes or plugged pipette tips to block aerosol production, UV irradiation of reaction components (not including *Taq* polymerase and PCR primers that can be inactivated by UV irradiation), use of small working aliquots, and frequent cleaning of equipment and laboratory surfaces with 10% bleach. An important precaution is the physical separation of the laboratory into

FIGURE 15.9. Hybrid capture assay. In step 1, target DNA is released and denatured. In step 2, RNA probe hybridizes with target DNA. In step 3, RNA–DNA hybrids are captured by an antibody to RNA–DNA hybrids that is bound to the sides of the reaction vessel. In step 4, an enzyme-conjugated antibody that recognizes RNA–DNA hybrids binds to the hybrids. In step 5, a chemiluminescent substrate is added, and light is emitted if hybrids have been formed. (Courtesy of Digene Corporation, Beltsville, Maryland.)

sections where (a) the specimen is prepared, (b) the PCR reaction is set up, (c) the PCR amplification reaction takes place, and (d) the detection of amplification products is carried out. After PCR has taken place, the reaction tube is opened only in the section of the laboratory devoted to product detection. Techniques such as the inclusion of uracil-N-glycosylase or psoralen and isopsoralen derivatives in the reaction mixture were developed to minimize the danger of PCR contamination.¹⁰⁴ Real-time PCR is less susceptible to contamination because product detection does not require manipulating the amplified product. For any form of nucleic acid testing, an additional concern is contamination from one specimen to another, which may occur during specimen handling in the

laboratory. Inclusion of negative controls in the reaction setup is important in order to detect this form of contamination.

Nucleotide Sequencing

Sequencing of PCR amplification products can be carried out using the cycle-sequencing reaction⁵⁷ or pyrosequencing. Sequence information can be used for several purposes including precise identification of a virus, genotyping, and the presence of mutations associated with antiviral drug resistance or unusual clinical manifestations. Genotypic resistance assays are performed most commonly for HIV, CMV, HBV, and influenza A virus (see section on antiviral susceptibility testing). For HBV, nucleotide sequencing of the nucleocapsid gene

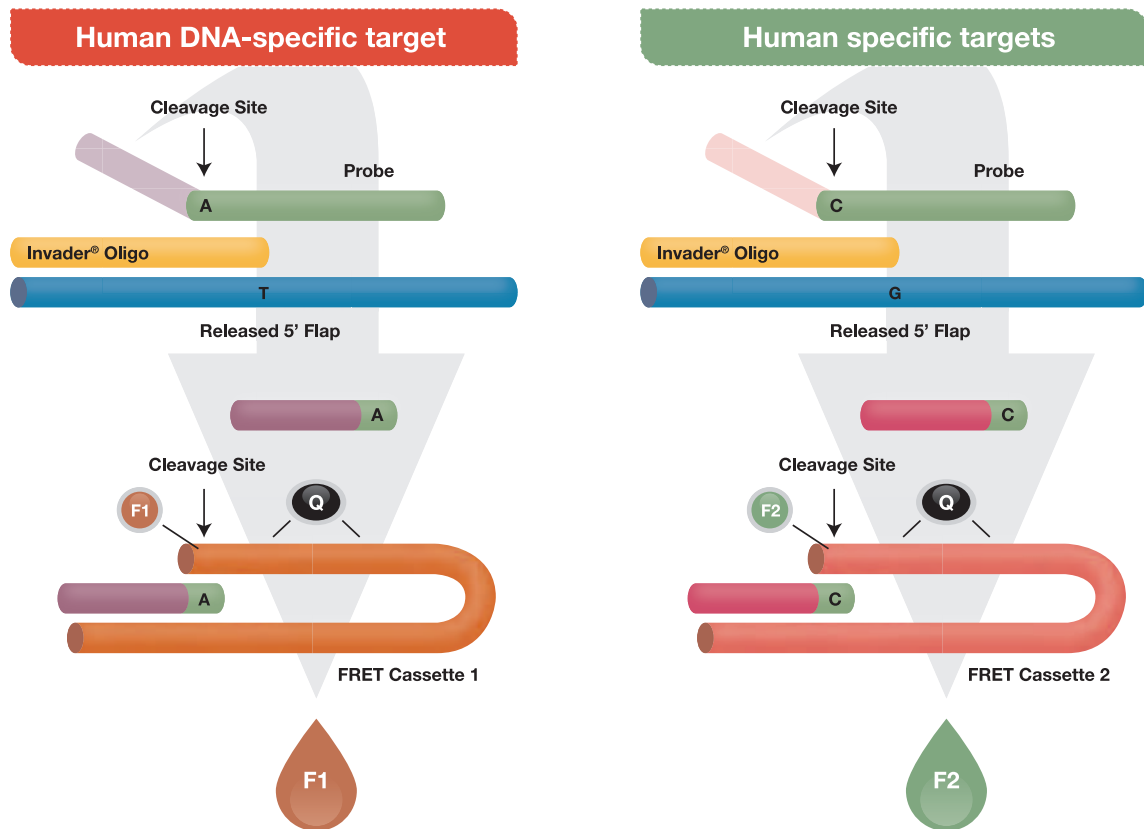

FIGURE 15.10. Invader assay. The **left side** of the figure shows a positive control reaction for human histone 2DNA and the **right side** shows the reaction to detect human papillomavirus (HPV). For each reaction, the probe oligo and the Invader oligo bind to the target, with a short region of overlap occurring at a targeted single nucleotide polymorphism (SNP). This results in a structure that is cleaved by the activity of an enzyme called “Cleavase,” releasing the 5′ end of the probe oligo at the position of overlap. The sequence of the released portion is homologous to the 3′ end of a third oligo, which includes a fluorophore (F1 for the human DNA reaction and F2 for the HPV reaction) and a quencher (Q) and is referred to in the figure as the FRET cassette. The hairpin configuration assumed by the FRET cassette brings the quencher sufficiently close to the fluorophore to allow its fluorescence to be quenched. Binding of the released portion of the probe oligo to the FRET cassette results in a region that is another substrate for Cleavase. The activity of Cleavase releases the fluorophore, resulting in generation of a fluorescent signal. (Courtesy of Hologic.)

and its associated promoter is also used for detection of core promoter and precore mutations, which have been associated with unusually severe disease and progression to chronic infection.⁹⁷ High-throughput (“next-generation”) sequencing will probably have important applications in diagnostic virology, including for antiviral susceptibility testing, for identification of viruses growing in cell culture that are not identifiable by conventional means,¹³⁰ and for discovery of known^{15,154} and novel viruses.^{20,99}

Microarray Technology

High-density microarrays consist of hundreds or thousands of oligonucleotide probes bound to a solid phase, usually a small silicon chip. Amplified nucleic acid can be hybridized to the array, and binding to specific probes can be identified. Use of probes representing all possible nucleotide sequence variations within a target sequence allows very rapid determination of nucleotide sequence.⁴⁵ Multiple sequence variants present within the specimen can also be detected. Microarray technology has the potential to allow simultaneous detection of multiple infectious disease pathogens, viral and nonviral. An early

application in diagnostic virology has been for rapid sequencing to detect HIV mutations associated with resistance to antiretroviral drugs.⁷⁰ In another application, sequences representing all sequenced viruses have been selected to create a microarray that can be used to discover unknown viruses. This microarray was successful in categorizing the agent of severe acute respiratory syndrome (SARS) as a new coronavirus.¹⁴⁵ The major application of microarray technology in diagnostic virology to date has been the use of liquid arrays, which are used for the simultaneous detection of multiple respiratory viruses, as exemplified by the xTAG RVP described later. Future uses of liquid arrays and other microarray technology under development include assays to detect multiple viruses (as well as other classes of pathogens) associated with gastroenteritis, sexually transmitted diseases, sepsis, and bioterrorism.

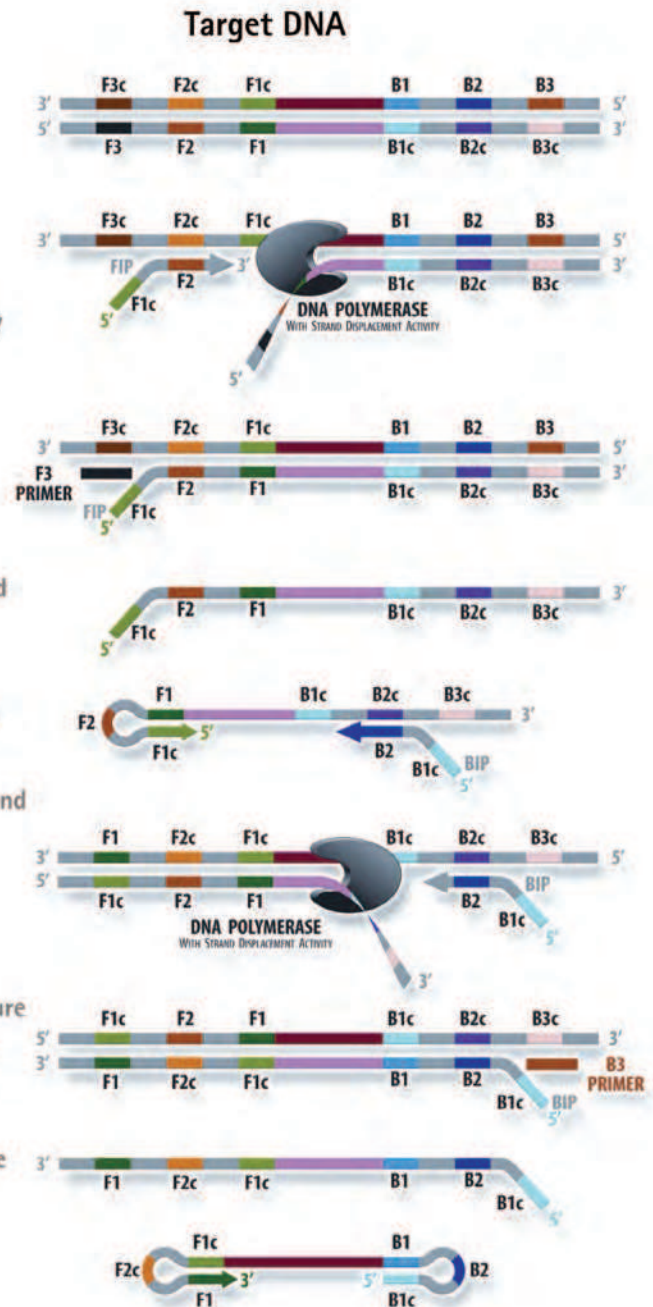

Commercial Nucleic Acid Amplification Platforms and Tests

GOVERNMENT REGULATION

In the United States, commercially marketed diagnostic tests and test platforms are regulated by the FDA. Before marketing

LAMP Process

1. Solution temperature at 60°–65° C
2. Forward Initiating Primer (FIP) anneals to Target Sequence
3. DNA Polymerase initiates synthesis that displaces single strand template DNA
4. Through polymerase activity, a strand complementary to the DNA template is formed
5. The F3 Primer anneals to the F3c Region
6. DNA Polymerase initiates synthesis and the FIP-linked complementary strand is replaced
7. This strand forms a "stem loop" at the 5' end due to complementary F1 and F1c regions
8. The BIP anneals to the 3' end of the "stem loop" strand
9. The B3 Primer anneals to the B3c target
10. From the 3' end, polymerase synthesizes a complementary DNA strand
11. DNA reverts from a Loop structure to a linear structure
12. The BIP linked complementary strand is displaced as a single strand
13. This strand forms stem-loops at either end due to the activity of the dual complementary primers
14. This is the starting structure for LAMP Cycling

A

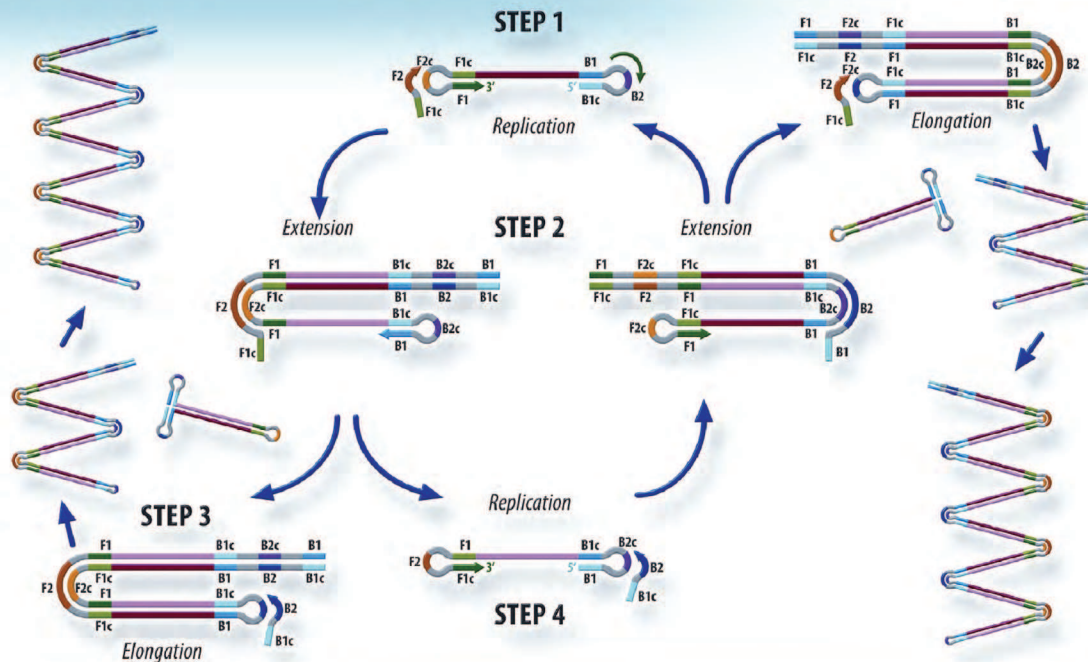

FIGURE 15.11. Loop-mediated amplification reaction (LAMP assay). A: Steps leading up to the formation of the "dumbbell" structure. (continued)

Cycling Amplification

A dumbbell-like DNA structure is quickly converted into a stem-loop DNA by self-primed DNA synthesis. FIP anneals to the single stranded region in the stem-loop DNA and primes strand displacement DNA synthesis, releasing the previously synthesized strand. This released single strand forms a stem-loop structure at the 3' end because of complementary B1c and B1 regions.

Then, starting from the 3' end of the B1 region, DNA synthesis starts using self-structure as a template, and releases FIP-linked complementary strand (STEP2).

The released single strand then forms a dumbbell-like structure as both ends have complementary F1 - F1c and B1c - B1 regions, respectively (STEP4).

This structure is the 'turn over' structure of the structure formed in STEP1. Similar to the STEPS 1 THROUGH 4, structure in STEP4 leads to self-primed DNA synthesis starting from the 3' end of the B1 region.

Furthermore, BIP anneals to the B2c region and primes strand displacement DNA synthesis, releasing the B1-primed DNA strand. Accordingly, similar structures to STEPS 2 AND 3 as well as the same structure as STEP 1 are produced. With the structure produced in STEP 3, the BIP anneals to the single strand B2c region, and DNA synthesis continues by displacing double stranded DNA sequence. As a result of this process, various sized structures consisting of alternately inverted repeats of the target sequence on the same strand are formed.

a test for diagnostic use, a manufacturer must receive authorization from the FDA. This authorization can take one of several forms. If there is no similar test on the market, the manufacturer must apply for premarket approval (PMA). This is a rigorous and expensive process that requires the manufacturer to provide evidence for the accuracy and utility of the proposed test. A test that is “substantially equivalent” to a test that has been previously approved or cleared by the FDA is cleared for use through a mechanism referred to as 510K, after the section of the Federal Food, Drug, and Cosmetic Act that describes the process. Some diagnostic test materials are marketed under the classification “analyte-specific reagent (ASR).” This term is used by the FDA to refer to reagents or materials, including nucleic acid primers and probes, that must meet certain specifications set by the FDA, including being produced utilizing current “good manufacturing practices.” In addition, clinical laboratory tests carried out using ASRs must have appropriate labeling appended to the reported results stating that the test was developed and validated by the laboratory and has not undergone FDA clearance or approval. ASRs are intended to be used as components of laboratory-developed tests and can be sold only to laboratories that are qualified under CLIA to perform highly complex testing. ASRs are excluded from the need for premarket approval by the FDA. They cannot be marketed as complete test kits and must be sold without instructions for use or claims regarding performance characteristics.

Individual laboratories may also develop their own assays that are intended for use only in that laboratory. These tests, referred to as “laboratory-developed tests” (sometimes also referred to as “home-brew assays”), are not actively regulated by the FDA, but instead are under the jurisdiction of CLIA passed by the U.S. Congress in 1988. Laboratory-developed tests may use ASRs as components of the test and may also use reagents obtained from diverse sources not specifically labeled as ASRs. The performance of laboratory-developed tests must be verified according to specific criteria established by CLIA.

OVERVIEW OF COMMERCIAL ASSAYS AND PLATFORMS

Since the last edition of this book, there has been a dramatic increase in molecular diagnostic tests and test platforms that have been approved or cleared by the FDA for the detection of pathogenic viruses. Tests and platforms approved or cleared by the FDA at the time this chapter was written are shown in Tables 15.8 and 15.9. These tables are adapted from tables that are maintained by the Association for Molecular Pathology (AMP) and are accessible on the AMP website (<http://www.amp.org>). No single platform permits the detection of all medically important viruses, so laboratories whose mission is broad-based viral diagnosis will need to employ multiple platforms. Currently, laboratories vary widely in the relative proportion of testing that is carried out using commercial platforms versus laboratory-developed tests. Likewise, laboratories that provide different types of service will employ different platforms. For example, hospital-based laboratories may emphasize platforms that provide rapid turnaround time, commercial laboratories may employ platforms that allow high specimen throughput, and government laboratories may employ platforms that allow for testing of viruses of public health significance. The following paragraphs describe several categories of commercial molecular diagnostic tests.

Multiplex Assays

Multiplex PCR refers to PCR reactions in which more than one primer set is incorporated into the reaction mix, allowing the detection of multiple targets. Multiplex assays may be developed either as commercial tests or as laboratory-developed tests. Currently, multiplex assays are being developed for important specimen types to amplify various viral and other microbial agents that are pathogenic at the specific body site. This process is most highly developed for respiratory samples, for which five different multiplex assays are currently cleared by the FDA.

The Proflu+ assay marketed by Prodesse (now Gen-Probe, San Diego, CA), the Simplexa Flu A/B & RSV Test assay marketed by Focus (Cypress, CA), and the Verigene RV+ (Nanosphere, Northbrook, IL) are multiplex real-time assays that use separate primer pairs to simultaneously amplify influenza A and B viruses and RSV plus an internal control. In the Proflu+ and Simplexa assays, unique probes for each virus and the internal control are labeled with separate fluorophores, allowing determination of which virus or viruses have been amplified. The Simplexa assay is run on the 3M Integrated Cycler, an innovative instrument produced by 3M (St. Paul, MN) that has the capability to run 96 assays in 1 hour. Multiple different specimens can be loaded on the instrument and multiple assays can be run simultaneously. The Verigene RV assay uses a very innovative system to detect amplified products in which the amplicons are captured by capture probes that are bound to specific sites on a microarray. Captured amplicons are then detected by binding of silver-coated gold nanospheres that have been tagged with oligonucleotides that are specific for the amplicons and are visualized by light scatter.

The xTAG Respiratory Virus Panel (RVP) marketed by Luminex (Toronto, Ontario, Canada) was the first large multiplex assay to be cleared by the FDA. This assay detects the following viruses in nasopharyngeal swabs: influenza A and B, influenza A subtypes H1 and H3, RSV A and B, parainfluenza 1 through 3, human metapneumovirus (hMPV), enterovirus/rhinovirus, and adenovirus.^{85,98} Primers for influenza A hemagglutinin subtype H5, parainfluenza 4, and coronaviruses OC43, 229E, NL63, HKU1, and SARS are also included in the reaction but are not currently cleared for use in the United States. The first step in the reaction is reverse transcription followed by a multiplex PCR reaction that includes primer sets for each target. The resulting amplicons are prepared for detection through a reaction called target-specific primer extension (TSPE). The 3' end of each of the primers used in TSPE is homologous to one of the amplicons from the multiplex PCR reaction. The 5' end of the primer consists of a short “tag” sequence that will be used to capture the TSPE product. During the extension reaction that follows annealing of the TSPE primers, biotin-labeled deoxycytidine triphosphate (dCTP) is incorporated into the primer extension product. Detection of the TSPE products uses a set of polystyrene microspheres composed of 100 members. Each member microsphere incorporates two fluorescent dyes in a unique ratio that allows identification by flow cytometry using two lasers, each of which emits light of the appropriate wavelength to excite one of the two fluorescent dyes. Bound to each member of the microsphere set is a short oligonucleotide (“antitag”) with sequence homology to one of the tags introduced in the TSPE reaction. These tags are specific for each amplicon amplified by the

multiplex reaction. Following the TSPE reaction, the reaction mix is incubated with the microspheres, allowing the microspheres to specifically capture any TSPE products that have been produced. A fluorescent detection signal is generated through the inclusion of streptavidin-phycoerythrin, which binds to the biotin molecules incorporated into the amplicons. As the microspheres pass through the flow cell, they are interrogated by the lasers, allowing identification of the specific microsphere set member and determination of whether or not a TSPE product has been bound. Computer software analyzes the fluorescent events and determines for each virus and internal control whether a threshold of detection has been surpassed. Recently a version that requires less time to complete, called xTAG RVP Fast, was cleared by the FDA for detection of influenza A, influenza A subtype H1, influenza A subtype H3, influenza B, RSV, hMPV, rhinovirus, and adenovirus.

The other large multiplex assay that has been approved by the FDA is the FilmArray Respiratory Panel, which was cleared by the FDA in 2011 for detection in nasopharyngeal swabs of the following viruses: influenza A and B; influenza A subtypes H1, H1 2009, and H3; RSV; hMPV; adenovirus; parainfluenza viruses 1 through 4; rhinovirus/enterovirus; and coronaviruses NL63 and HKU1.¹¹⁰ Extraction, amplification, and detection are carried out in a self-contained unit referred to as a “pouch.” Nucleic acid extraction is accomplished using magnetic beads. The nucleic acid amplification that follows is a multiplex nested PCR assay. The first amplification reaction is a multiplex reaction containing outer primers for each target virus. The reaction mix is then diluted and combined with a new primer-free master mix that contains the fluorescent dye LC Green Plus, which binds to dsDNA. This mix is then moved by microfluidic techniques into an array of individual wells, each of which contains inner primers specific for one target virus. Each target is represented in at least three wells. Production of viral amplicons is confirmed by analyzing melting curves. The entire process from inoculation of sample to availability of results takes approximately 1 hour, with only 2 minutes of hands-on time. The manufacturer also plans to develop a test for gastroenteritis that will include but not be limited to viruses.

Integrated Platforms. The term *integrated platform* refers to test platforms in which nucleic acid extraction, amplification, and product detection are carried out within the same device or instrument. These platforms represent an important advance in diagnostic microbiology because their simplicity allows them to be performed in many laboratories that would not otherwise be able to provide viral diagnostic testing. In fact, they are so simple that they could be performed in a physician's office, although they do not currently have CLIA-waived status, which would permit testing outside of laboratories approved for “high-complexity” testing. To date, two integrated platforms have been approved or cleared by the FDA. The first is the GeneXpert Real-time PCR system, marketed by Cepheid (Sunnyvale, CA). This platform employs test cartridges into which a specimen is inoculated. The cartridge is inserted into the GeneXpert instrument, which performs nucleic acid extraction, amplification, and product detection without any intervention by the user. Tests for enteroviruses⁶⁹ and for influenza A and B viruses¹⁰⁵ have currently been cleared by the FDA. The enterovirus assay requires a total of approximately 2½ hours to perform, while the influenza assay requires less

than 1 hour. Several GeneXpert bacterial assays have also been cleared by the FDA. The second integrated platform cleared by the FDA is the FilmArray, described previously.

HIGH-THROUGHPUT QUANTITATIVE SYSTEMS

Commercial systems that provide standardized quantitative testing for HIV and HCV RNA and HBV DNA have been approved by the FDA. These systems are the Roche COBAS AmpliPrep/COBAS TaqMan and the Abbott m2000. Both systems include separate automated instruments for nucleic acid extraction and real-time PCR. While these systems are highly automated, they require more hands-on time from laboratory personnel than the truly integrated platforms. Both systems have the capability for moderate to high throughput. Test results are intended for diagnosis, to determine the need for treatment, and to monitor the response to therapy. Tests for quantitative detection of HIV, HCV, and HBV have been approved on both systems. The m2000 system is also FDA approved for detection of *Chlamydia trachomatis* and *Neisseria gonorrhoea*. Outside of the United States, additional viral tests are available for the m2000, including HCV genotyping and detection of CMV, Epstein-Barr virus (EBV), HPV, *C. trachomatis*, and *N. gonorrhoea*.

Specialized highly automated platforms have also been approved by the FDA for screening donated blood. The Procleix Tigris system has been developed by Gen-Probe in collaboration with Novartis Diagnostics (Emeryville, CA). This is a highly automated instrument that uses FDA-cleared assays (Procleix Ultrio and Ultrio Plus) to test for HIV, HCV, HBV, and West Nile virus (Procleix West Nile Virus Assay). The tests for RNA viruses use the TMA reaction for amplifying RNA. Roche has developed the COBAS s201 system for screening donated blood. This system includes the COBAS AmpliPrep instrument for nucleic acid extraction and the COBAS TaqMan 96 analyzer for performing real-time PCR. The system provides testing for HIV, HCV, HBV, and West Nile virus (TaqScreen MPX Test and TaqScreen West Nile Virus test). Non-real-time PCR assays (COBAS AmpliScreen) have also been approved by the FDA for screening donated blood for HIV, HCV, and HBV.

Serology

Measurement of antiviral antibodies was one of the first methods used for the specific diagnosis of viral infections and it remains an important tool in the diagnostic virology laboratory. The role of serology can be for the diagnosis of acute or current infection or for the determination of immune status to specific viruses. Serologic diagnosis is important for viruses that cannot be cultured readily or for which culture is slow or otherwise impractical. Viruses for which serology is useful in diagnosing acute infection are shown in Table 15.10. Serology is uniquely useful for defining immunity with respect to specific viruses. It is important to use sensitive assays such as EIA for this purpose, because antibody levels indicative of past infection can decline to very low levels years after the infection. The specific assay used must also be selected with care to ensure that it measures antibodies that correlate with immunity. Viruses for which serologic testing is used to determine immune status are shown in Table 15.11.

Kinetics of the Antibody Response

Serologic diagnosis is based on the kinetics of the antibody response to viral infection. Virus-specific antibodies are absent

^bVirus-specific IgM assays are used for hepatitis A, B, and E.

in a susceptible individual but typically become detectable several weeks after the onset of infection. Virus-specific IgM antibodies are often detectable for a short period before virus-specific IgG antibodies. The IgM response tends to decline within approximately 1 to 2 months, although low levels can persist for 1 year or more in some viral infections. IgG antibodies are much more long-lasting and can persist for the life span of the individual. Thus, the absence of virus-specific IgG and IgM antibodies signifies susceptibility to infection; the presence of virus-specific IgM antibodies, with or without virus-specific IgG antibodies, signifies current or very recent infection; and the presence of virus-specific IgG but not IgM antibodies signifies past infection. The latter pattern often, but not always, indicates immunity to subsequent infection.

An alternative serologic approach to the diagnosis of recent infection is based on the concept that the avidity of antigen-specific antibodies increases as the immune response matures.²⁸ Thus, antibodies produced shortly after infection have low affinity for the causative agent, and antibodies produced late after infection have high affinity. Detection of low-affinity antibodies has been used to diagnose recent infection with CMV,²⁷ rubella,¹¹⁶ and HIV.¹²⁹

The relationship between the onset of clinical manifestations of infection and the presence of virus-specific antibodies depends on the incubation period of the infection. In infections with short incubation periods (e.g., acute respiratory infections), antibodies are absent at the onset of symptoms. In viruses with incubation periods of 1 month or longer, however, virus-specific IgG and IgM antibodies are typically present at the onset of symptoms.

Serology in Reinfection and Reactivation

The serologic diagnoses of reinfection and reactivated infection are more complicated than that of initial infection. In both of these cases, the infection occurs in an individual with preexisting, virus-specific IgG antibodies. In reinfection an anamnestic response may occur that results in an increase in the level of virus-specific IgG antibodies with continued absence of virus-specific IgM antibodies. Reactivation of latent infection, for example, in the case of some herpesvirus infections, may result in the appearance of virus-specific IgM as well as IgG antibodies.

Serology in Chronic Infections

The interpretation of serology is unique for viruses that typically cause chronic infection (e.g., HIV) and the related retroviruses human T-cell lymphoma or leukemia virus (HTLV) types 1 and 2. For these agents, the detection of antibodies of any isotype to these viruses (in the absence of artificial immunization) virtually always signifies current infection. In the case of HCV, the confirmed presence of antibodies to the virus corresponds to active infection in approximately 85% of individuals. A recent innovation is the development of tests that simultaneously measure HIV p24 antigen in addition to HIV antibodies. Because p24 antigen may appear some days before the appearance of HIV antibodies, the combined test decreases the “window” during which a recently infected individual is serologically negative but capable of transmitting infection.¹⁰⁰ The Abbott Architect HIV Ag/Ab Combo assay was recently approved by the FDA as an aid in the diagnosis of HIV-1 or -2 infection.

Serologic Assays

BINDING ASSAYS

The most widely used assays are those that directly measure binding of antibodies to viral antigens. Examples of binding assays include EIA, radioimmunoassay (RIA), and the indirect immunofluorescent antibody assay (IFA). Binding assays can be used in many different formats. In one common format, a viral antigen, which can consist of virally infected cells, a purified viral preparation, or a recombinant viral protein, is attached to a solid surface such as the inner surface of the well of a microtiter tray, a plastic bead, or a microscope slide in the case of IFA. Serum is added, allowing the binding of antiviral antibodies that might be present in the serum. After an appropriate incubation period, the serum is removed and the well is extensively washed. The next step is the addition of a second antibody (also referred to as a detector antibody) with specificity for human immunoglobulins. The second antibody is typically a mouse monoclonal or a polyclonal antibody from a nonhuman species. It is linked to an enzyme such as horseradish peroxidase. The second antibody binds to any human antibody present (ideally, because of specific binding to the viral antigen). The well is again extensively washed, and the presence of the second antibody is detected based on a colorimetric, radiometric, or fluorescent signal. An

important advantage of binding assays is that they can be modified to detect IgM- or IgA-specific antiviral antibodies through the use of isotype-specific detector antibodies.

IMMUNOBINDING ASSAYS

The western blot and related recombinant immunobinding assays are binding assays that allow the identification of antibodies to specific viral proteins. In the western blot assay, viral antigens present in infected cells are denatured, separated by gel electrophoresis, transferred to a membrane, and allowed to react with the serum specimen. Binding of antiviral antibodies is detected through the use of labeled detector antibodies. The western blot is cumbersome but provides a very high level of specificity because of the ability to identify binding to individual viral proteins and the production of a characteristic blot fingerprint. Thus, its main application in diagnostic laboratories is the confirmation of screening assays (e.g., EIA) that are less specific. For example, until recently, the western blot was widely used to confirm a positive HIV EIA. Western blot is also considered the gold standard in determining the type specificity of HSV antibodies. The recombinant immunobinding assay differs from the western blot in that specific viral antigens are produced in *in vitro* expression systems and artificially attached to membranes in a predetermined configuration, often in dots or in bands. The membranes are then incubated with serum, and bound antibodies are detected, as in the western blot. Because the antigens used in the immunobinding assay are not denatured as they are in routine western blots, these assays may have advantages in detection of antibodies to conformational epitopes. A recombinant immunobinding assay is used to confirm positive hepatitis C EIA results.

FUNCTIONAL ASSAYS

Functional assays are based on detection of specific activities resulting from the binding of specific antibodies to viral antigens. An important example is the neutralization assay, which measures the ability of antibodies to block viral infectivity. In neutralization assays, serial dilutions of the serum to be tested are incubated with a standardized quantity of infectious virus. After a short incubation period, the serum-virus mixtures are added to cells that support the growth of the virus, in parallel with a similar inoculum of virus that has not been incubated with serum. The neutralizing antibody titer is the highest serum dilution that prevents infection of the cells. The neutralization assay correlates well with protection from infection and is sometimes considered the standard against which other serologic assays should be measured. Because it is cumbersome and expensive, the neutralization assay is now rarely used in routine diagnostic laboratories. Other examples of functional assays are the hemagglutination-inhibition assay, in which the presence of antiviral antibodies is detected by their ability to block virus-induced hemagglutination, and the complement fixation assay, which measures the ability of antiviral antibodies to fix complement, preventing the complement from lysing indicator erythrocytes. Although hemagglutination-inhibition and complement fixation assays have been widely used in the past, they are increasingly being replaced by binding assays.

AGGLUTINATION ASSAYS

Viral antigens can be bound to a variety of particles, including fixed erythrocytes and latex particles. Agglutination assays are performed by mixing dilutions of serum with a suspension of antigen-coated particles. The agglutination titer is the

highest serum dilution that results in visible agglutination of particles. The advantage of agglutination assays is simplicity; they are rapid and do not require sophisticated equipment. Therefore, they are well suited for *stat* testing and for use under field conditions. For example, a rapid latex agglutination assay for varicella antibodies can be used for rapid determination of the varicella immune status of health care personnel who are exposed to a patient with varicella.

Virus-Specific IgM Assays

Assays for virus-specific IgM antibodies are important because they often allow a specific diagnosis of an acute infection to be made based on analysis of a single serum specimen obtained during the acute phase of illness. These assays are most likely to be useful in diseases with incubation periods that are sufficiently long so that virus-specific IgM levels are present at detectable levels at the onset of illness. Hepatitis A provides an excellent example; because of its incubation period of 2 to 6 weeks, hepatitis A IgM antibodies are virtually always detectable at the time patients seek medical care.

A number of methods are used to measure virus-specific IgM antibodies. Two older methods include (a) separating IgG and IgM fractions before performing the virus-specific antibody assay and (b) performing the virus-specific assay before and after procedures, such as treatment with β -mercaptoethanol, that selectively destroy IgM antibodies. Many modern virus-specific IgM antibody assays use IFA or EIA with a detector antibody that binds only to human IgM. The IgM capture assay is an alternative approach in which IgM antibodies present in the serum sample being tested are first *captured* using an antibody specific for human IgM. A preparation of viral antigen is added, followed by an enzyme-labeled antibody specific for the viral antigen. Binding is detected by the addition of the appropriate enzyme substrate.

Virus-specific IgM assays have several potential pitfalls and must be interpreted in conjunction with clinical findings. False-positive results can occur if the serum being tested contains rheumatoid factor (IgM antibodies to human IgG) plus virus-specific IgG antibodies that form complexes that may be falsely detected by the assay as virus-specific IgM antibodies. This problem can be avoided by pretreatment of the serum to remove either rheumatoid factor or IgG antibodies. One or the other of these pretreatments is included routinely in many commercial virus-specific IgM antibody assays. False-negative results can occur if the serum being tested contains high levels of virus-specific IgG antibodies that may compete with the virus-specific IgM antibodies. The IgM-capture assay configuration avoids this problem, as does serum pretreatment to remove IgG.

Complexities in the nature of the IgM antibody response must also be considered in interpreting virus-specific IgM antibody tests. In some patients, the IgM antibody response is transient or low level, leading to failure to detect virus-specific IgM antibodies, whereas in others, low levels of IgM antibodies may persist for 1 year or longer, decreasing the specificity of the assay as an indicator of very recent infection. In herpesvirus infections, IgM antibodies can sometimes be detected in reactivations as well as in primary infection.

Saliva and Urine Assays

Virus-specific antibodies can often be detected in saliva and urine. These body substances are attractive for use in serologic

assays because they avoid the need for phlebotomy. Assays for HIV antibodies in these fluids are commercially available and have performance characteristics similar to assays carried out on serum.^{35,138}

Cerebrospinal Fluid Serology

Serologic testing can be applied to CSF for the diagnosis of central nervous system (CNS) infection. For unusual viruses (e.g., rabies), the presence of any virus-specific antibodies within the CSF is diagnostic of active infection. For the diagnosis of encephalitis caused by the alphaviruses, bunyaviruses, or flaviviruses, the presence of virus-specific antibodies in CSF is highly suspicious and the presence of virus-specific IgM antibodies in CSF is diagnostic. For more common viruses (e.g., herpesviruses) or the common respiratory viruses, the mere presence of virus-specific antibodies in CSF is not diagnostic of CNS infection because antibodies produced in the blood are present in the CSF even in the absence of CNS infection. The problem is further complicated by the fact that defects in the blood–brain barrier that can occur during many neurologic diseases can increase the passage of antibodies from blood to CSF. Therefore, for the common viruses, intrathecal synthesis of specific antiviral antibodies must be demonstrated to provide evidence of CNS infection.

Intrathecal synthesis of a specific antiviral antibody is evaluated by determining the quotient of two ratios: (a) the ratio of specific antiviral antibody level in CSF to the level in serum, and (b) the ratio of total IgG in CSF to total IgG in serum ($\text{CSF}_{\text{specific antibody}} \cdot \text{serum}_{\text{specific antibody}}$ divided by $\text{CSF}_{\text{IgG}} \cdot \text{serum}_{\text{IgG}}$). A quotient greater than 1.5 is evidence of intrathecal antibody synthesis of the specific antibody. The antibody assay used to measure the specific antiviral antibody must have certain special characteristics. First, it must be very sensitive, because CSF antibody levels are usually low (~1,000 times less than serum levels). Second, it must be capable of providing a quantitative result that allows calculation of the CSF-to-serum ratio of specific antibody level. EIA is usually used, but testing of a series of dilutions of CSF and serum is required to obtain linear quantitative estimates of antibody level suitable for calculating the necessary ratio. Because of the complexities involved, accurate determination of intrathecal antibody synthesis of specific antiviral antibodies is performed in only a limited number of reference laboratories.

Measurement of intrathecal antibody synthesis has been used in a variety of CNS infections. The applications for which experience is most extensive are encephalitis caused by HSV and VZV. In HSV encephalitis, the utility of determinations of intrathecal antibody synthesis is limited because intrathecal antibody synthesis may not be detectable until 7 to 10 days after the onset of illness. Interestingly, intrathecal antibody synthesis can persist for years after the acute infection. Therefore, the main application is in cases in which specimens were not available early in the illness to allow a definitive diagnosis based on PCR. A caveat concerning diagnosis by demonstration of intrathecal antibody synthesis is that nonspecific polyclonal intrathecal antibody synthesis can occur in some diseases (e.g., multiple sclerosis).¹¹³ This pitfall can be avoided by evaluating intrathecal synthesis of antibodies to at least one other virus other than the one of primary interest. Serologic diagnosis has been shown to be more sensitive than PCR for diagnosis of VZV vasculopathy.⁹¹ This is explained partly by the fact that

CSF samples from some patients in this study were obtained months after the onset of neurologic manifestations.

Antiviral Susceptibility Testing

In recent years, antiviral drugs have been licensed for the treatment of infections caused by HSV, VZV, CMV, influenza A and B, RSV, HIV, HCV, and HBV. Not surprisingly, increasing use of these drugs has been accompanied by the appearance of antiviral drug resistance. Testing for resistance may be required for optimal patient management. Antiviral drug susceptibility testing is performed in some diagnostic virology laboratories and is also available through reference laboratories.

Phenotypic Assays

Antiviral susceptibility testing is divided into phenotypic and genotypic methods. Phenotypic methods analyze the effect of antiviral drugs on the replication of virus, which can be measured by infectivity, viral antigen or nucleic acid production, or effect on the activity of a viral enzyme such as influenza neuraminidase. Phenotypic assays are important because they directly measure the effects of antiviral drugs on viral replication. In addition, they are more universal than genotypic assays because they can be used when the genetic basis for resistance is unknown. In the case of HIV, phenotypic assays are useful in analyzing viruses in which the presence of multiple mutations makes it difficult to predict phenotype from genotypic data. Finally, phenotypic assays must be used to determine the significance of candidate mutations found in drug-resistant isolates. However, from a practical standpoint, phenotypic assays tend to be labor-intensive, slow, and poorly standardized. In addition, there is a theoretical concern that the growth of the virus in cell culture may lead to selection of nonrepresentative viral variants, especially because antiviral resistance may in some instances be associated with decreased viral fitness. For these reasons, phenotypic assays are not performed in most diagnostic virology laboratories. Table 15.12 shows recommended *cut-offs* that define resistance to several drugs used for HSV and CMV infections.

The plaque assay was the traditional method for performing phenotypic susceptibility testing. However, this method is rarely used in diagnostic virology laboratories for the reasons mentioned previously and will not be discussed further here. Assays measuring viral antigen or nucleic acid production are alternatives to infectivity-based assays. A variety of assays have been used in individual laboratories, but they are not commercially available. The ELVIS assay illustrated in Figure 15.3 has also been adapted for the performance of antiviral susceptibility testing.^{128,134} For influenza, resistance to neuraminidase inhibitors has been measured using neuraminidase inhibition assays based on either fluorescent or chemiluminescent signal generation.^{12,92,93}

Recombinant phenotypic assays have been developed and widely used for HIV. These assays involve insertion of HIV genes that are targets for antiretroviral drugs (polymerase, protease, integrase) from a patient being evaluated into a vector consisting of a rapidly replicating laboratory strain of HIV that also contains a reporter gene (e.g., luciferase) that is used to measure viral growth.¹⁰² These assays allow relatively rapid testing of the susceptibility of HIV to multiple drugs as well as to drug combinations. Commercial tests have been developed by Monogram Biosciences (San Francisco, CA) and Virco

TABLE 15.12 Cut-Offs for Antiviral Susceptibility Testing for Herpes Simplex Virus (HSV) and Cytomegalovirus (CMV) Using the Plaque Reduction Assay

Virus (reference)	Drug	Cut-off (μM)		
		Sensitive	Intermediate	Resistant
HSV (117)	Acyclovir	<8		≥ 8
	Foscarnet	<330		≥ 330
CMV (18,84)	Ganciclovir	≤ 6	6–12	>12
	Foscarnet	≤ 400		>400
	Cidofovir	≤ 2		>4

(Antwerp, Belgium) and are available in the United States through national reference laboratories. A special case is the HIV drug maraviroc, which blocks HIV entry by binding to the CCR5 receptor. Viruses that use the CXCR4 receptor rather than the CCR5 receptor are resistant to maraviroc. A commercial assay called Trofile (Monogram Biosciences)¹⁵⁰ is used to predict response to maraviroc by determining the receptor tropism of a patient's isolate.

Genotypic Assays

Genotypic assays test for the genetic basis for resistant phenotypes. A variety of methods are used, including detection of restriction fragment length polymorphisms, PCR assays that detect mutations by virtue of differential primer or probe binding, and nucleotide sequencing. With rapid improvements in sequencing technology including the development of pyrosequencing, sequencing-based methods are becoming increasingly used. Genotypic assays are informative only when the genetic basis for resistance is known and are most useful when the resistance being evaluated is accounted for by a limited number of genetic changes.

Genotypic assays have been most widely used for CMV, HIV, HBV, and influenza A, because phenotypic assays for these viruses are slow and expensive or not widely available. Application of genotypic assays requires an extensive body of knowledge concerning the effect of specific mutations on antiviral resistance. Some single mutations may confer high-level resistance, while others may confer only partial resistance, and others are not associated with resistance at all.

For CMV, resistance to the currently FDA-approved drugs ganciclovir, foscarnet, and cidofovir has been related to mutations in the phosphotransferase (*UL97*) and polymerase (*UL54*) genes.^{18,84} Most laboratories now use sequencing to detect these mutations. Because ganciclovir-resistance mutations generally arise first in the *UL97* gene, some laboratories sequence this gene first, proceeding to sequencing *UL54* only if no significant mutations are detected in *UL97*, or if the patient is being treated with foscarnet or cidofovir, which exert their antiviral effect by inhibiting this gene. Different mutations within *UL97* or *UL54* are associated with different levels of antiviral resistance.⁸⁴

For HIV, genotypic testing for resistance is commonly used by physicians in the developed world in the management of antiretroviral drug therapy. This testing involves RT-PCR amplification of regions of the polymerase and protease genes and sometimes the integrase gene, followed by nucleotide sequencing of the amplicons. Certain mutations are highly

associated with phenotypic resistance and drug failure, whereas the significance of other mutations found in drug-resistant strains is less clear. Interpretation of HIV genotypic testing is most straightforward in patients who are not highly drug experienced and have relatively small numbers of mutations. Patients who have been treated more extensively may have multiple interacting mutations and may also have mutations that lie outside of the segments that are sequenced but nevertheless affect susceptibility to antiretroviral drugs.⁴³ Several FDA-approved sequencing systems are commercially available to detect HIV drug resistance mutations, including the ViroSeq system marketed by Celera Diagnostics (Alameda, CA) and the TruGene system marketed by Siemens (Deerfield, IL). High-throughput sequencing can be used to detect rare drug-resistant mutants that make up a small percentage of viral genomes.¹²² The clinical significance of small minority populations of drug-resistant mutants is still under investigation.¹¹

Resistance testing for influenza is related to the two existing classes of influenza antiviral drugs, the adamantanes and the neuroaminidase inhibitors. Resistance to the adamantanes occurs when there are mutations at positions 26, 27, 30, 31, or 34 in the gene encoding the M2 matrix protein, which is the target of the drugs.¹¹ Resistance to the neuraminidase inhibitors is related to specific mutations in the gene encoding neuraminidase, especially a histidine to tyrosine change at position 274 (N2 numbering), designated H274Y. This mutation became widespread during the 2007–2008 influenza season.^{24,50} Pyrosequencing has been effectively used to detect these mutations,²³ as have a variety of PCR-based assays.^{19,151}

The presence of resistance of HBV to antiviral agents is detected by sequencing of the DNA polymerase gene. Genotypic testing for HSV is less useful than phenotypic testing because of the diverse genetic loci within the HSV thymidine kinase and polymerase genes that can account for resistance.³⁷

SELECTED CLINICAL PROBLEMS

Tables 15.13 through 15.18 provide information related to specific areas of diagnostic virology not covered elsewhere in the chapter.

VIRUS DISCOVERY

Experimental methodologies used for viral discovery have traditionally relied on classic approaches such as electron

TABLE 15.13 Laboratory Diagnosis of Human Herpesvirus Infections

Virus	Clinical problem	Test(s)	Specimen
Herpes simplex	Mucocutaneous lesions	Culture, NAAT, FA stain	Swab of lesion
	Encephalitis or meningitis	NAAT	CSF
Varicella-zoster	Mucocutaneous lesions	Culture, NAAT, FA stain	Swab of lesion
	Encephalitis or meningitis	NAAT	CSF
	CNS vasculopathy	Intrathecal antibody synthesis, NAAT ^a	Serum or plasma plus CSF
Cytomegalovirus	Systemic infection in immunocompromised individual	Quantitative NAAT, pp65 antigenemia assay	Plasma or whole blood
	Mononucleosis syndrome in nonimmunocompromised individual	CMV IgM antibody assay, NAAT	Serum or plasma for antibody assay, plasma or whole blood for NAAT
	Tissue-invasive disease (e.g., involving the gastrointestinal or respiratory tract)	Histology, immunohistochemistry <i>in situ</i> hybridization, culture, NAAT	Tissue from involved organ
	Encephalitis	NAAT	CSF
	Retinitis	NAAT	Vitreous or aqueous fluid
Epstein-Barr virus (EBV)	Infectious mononucleosis	Heterophile antibody assay, ^b IgM antibodies to the viral capsid antigen	Serum or plasma
	Posttransplant lymphoproliferative disorder	Quantitative NAAT	Whole blood or plasma
	Primary central nervous system lymphoma	NAAT	CSF
	Encephalitis or meningitis	NAAT ^c	CSF ^c
Human herpesviruses types 6 (HHV-6) and 7 (HHV-7)	Acute infection ^d	NAAT, ^e IgM antibody assay, IgG avidity assay ¹⁴⁷	Plasma (NAAT), plasma or serum for IgM antibody assay or IgG avidity assay ¹⁴⁷
	Systemic infection in immunocompromised individual	NAAT ^e	Whole blood or plasma ^e
	Encephalitis	NAAT ^e	CSF
Human herpesvirus type 8 (HHV-8) (Kaposi sarcoma virus)	Systemic infection ^f	NAAT	Blood or body fluid

CSF, cerebrospinal fluid; FA, fluorescent antibody; Ig, immunoglobulin; NAAT, nucleic acid amplification test.

^aIntrathecal antibody synthesis has been shown to be more sensitive than NAAT for diagnosis of varicella-zoster virus central nervous system vasculopathy.⁹¹

^bSlide tests or other modified heterophile assays are usually used.

^cShould be performed only in the setting of primary EBV infection. In other clinical settings, specificity and positive predictive values are low.

^dSome but not all cases have a rash and are diagnosed as roseola.

^eApproximately 1% of the population has chromosomal integration of HHV-6 and has very high levels of HHV-6 DNA in blood and tissue, which is not indicative of disease attributable to HHV-6. Chromosomal integration in immunocompetent patients can be excluded by testing a follow-up sample (those with chromosomal integration will have persistently high levels of HHV-6 DNA) or a pretransplant sample from the transplant recipient (those with chromosomal integration will have high levels of HHV-6 DNA in the pretransplant sample).

^fSystemic HHV-8 infection may be associated with body cavity lymphoma or multicentric Castleman disease.

microscopy, cell culture, and antibody-based detection. Despite the success of these approaches, which have resulted in the discovery of many viruses throughout the years, each of these methods suffers from significant limitations. For example, electron microscopy requires high viral titers and may not provide the necessary resolution to unambiguously identify the type of virus even when viral particles are observed. Many viruses cannot be cultured, and those that can often require very specific cell types; crucially, there is no universal cell line capable of broadly supporting growth of all, or even a majority of, known viruses. Antibody-based methods are limited

in breadth, require the development of specific reagents for a given viral group, and, most critically, require selection of specific candidates based on prior knowledge in order to be useful in identifying a virus. Due to these limitations, there have been ongoing efforts to develop additional complementary strategies for detecting and discovering novel viruses. In the last decade of the 20th century, various molecular methods were developed in efforts to circumvent limitations of these classic approaches. These molecular methods, including library immunoscreening, degenerate PCR, and representational difference analysis, led to the discovery of many clinically important viruses including

TABLE 15.14 Laboratory Diagnosis of Viral Respiratory and Gastrointestinal Tract Infections

Virus	Test method	Comments
Respiratory tract infections		
Influenza A, B	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT
	Culture	Less sensitive than NAAT, requires viable virus
	Antigen detection	Low sensitivity, especially for pandemic 2009 H1N1 virus
Respiratory syncytial	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT
	Culture	Requires viable virus
	Rapid tests	Less sensitive than other methods
Parainfluenza	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT
	Culture	Requires viable virus
Human metapneumovirus	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT
Rhinovirus	NAAT	Most sensitive test; primers and probes must be selected carefully to detect all serotypes/genotypes. May be difficult or impossible to distinguish from enteroviruses
	Culture	Requires viable virus; is less sensitive than NAAT. Clade C rhinoviruses have not been successfully cultured as of time of writing
Coronaviruses (OC43, 229E, NL63, HKU1)	NAAT	Most sensitive test
Adenoviruses	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT or culture
	FA	Less sensitive than culture
Gastrointestinal tract infections		
Rotavirus	Antigen detection	Very sensitive
Norovirus	NAAT	Most sensitive test
	ELISA	Less sensitive than NAAT
Adenoviruses (group F, serotypes 40 and 41)	ELISA	Specific assay for serotypes 40 and 41
	NAAT	Most sensitive test
Astroviruses	NAAT	Most sensitive test

ELISA, enzyme-linked immunosorbent assay; FA, fluorescent antibody; NAAT, nucleic acid amplification test.

HCV, Kaposi sarcoma herpesvirus (KSHV), and others. As these methods have been the subject of other reviews,⁶⁵ they will not be discussed in detail here.

The 21st century has witnessed a revolution in the field of virus discovery as evidenced by the dramatic increase in the rate of identification of novel viruses. This increase has been driven largely by the advent of the genomic era, which has created novel sequencing technologies that in turn have geometrically increased the volume of sequencing data that can be generated. The combination of increased sequences in public databases and increased sequencing capacity has enabled the development of new, sophisticated sequence-based approaches for viral detection and discovery. Even existing methods, such as consensus PCR approaches, have benefited from the geometric growth in sequence databases. With the availability of many more viral genome sequences, improved consensus PCR primers can be designed for many viral taxa.

All of the recently developed viral discovery methods are based on detection of viral nucleic acids. Fundamentally, the major challenge in sequence-based viral discovery is identifying the relatively few copies of viral DNA or RNA in specimens that typically contain a vast excess of host genomic DNA and/

or RNA. In theory, given unlimited sequencing capacity, there would be no need to be concerned with the host; exhaustive direct sequencing of a given sample should reveal the presence of any viral sequences in the sample no matter how low the abundance of the virus. However, practical limitations on sequencing, either in terms of sheer capacity or cost, have until recently required that additional methods be employed to effectively increase the relative percentage of viral sequence to host sequence. For example, propagation of a virus in cell culture is one means of increasing the relative abundance of viral sequences. Physical purification of virions, by ultracentrifugation or nuclease treatment to eliminate nonencapsidated nucleic acids, is another means of enriching for viral sequences. Subtractive hybridization strategies achieve a similar end point by physically reducing the amount of host sequences. However, we are rapidly approaching a point where sequencing capacity and costs are no longer limiting.

One potential limitation in sequence-based virus discovery is the quantity of nucleic acids available for sequencing. To circumvent this challenge, multiple experimental approaches to increase the total abundance of nucleic acids to levels amenable to further analysis have also been developed. An essential feature

TABLE 15.15 Laboratory Diagnosis of Central Nervous System Infections

Syndrome	Virus	Method ^a
Meningitis	Enterovirus	NAAT
	Herpes simplex virus	NAAT
	Varicella-zoster virus	NAAT
	Human immunodeficiency virus	NAAT on plasma
Encephalitis in nonimmunosuppressed individuals	Herpes simplex	NAAT
	West Nile virus and other arboviruses	IgM antibody assay on serum and CSF ^b
	Varicella-zoster virus	NAAT, intrathecal antibody synthesis ^c
	Epstein-Barr virus	NAAT, IgM antibody assay on serum and plasma
	HHV-6	NAAT
	Rabies	NAAT on CSF and saliva, rabies antibody assay on CSF and serum, ^d FA stain of skin biopsy from nape of neck
	Mumps	NAAT on CSF and saliva, IgM antibody assay on serum
	Lymphocytic choriomeningitis virus	IgG and IgM antibody assays on CSF and serum (acute and convalescent samples), NAAT, culture
Encephalitis in immunosuppressed individuals	Cytomegalovirus	NAAT
	Epstein-Barr virus	NAAT
	Varicella-zoster virus	NAAT, intrathecal antibody synthesis ^c
	JC virus	NAAT

CSF, cerebrospinal fluid; HHV-6, human herpesvirus type 6; Ig, immunoglobulin; NAAT, nucleic acid amplification test.

^aIndicated test is performed on CSF unless otherwise indicated.

^bTesting should be performed on CSF and serum. Testing of CSF is more specific for current infection.

^cDetection of intrathecal antibody synthesis has been shown to be more sensitive than NAAT for the diagnosis of varicella-zoster virus central nervous system vasculopathy.⁹¹

^dCSF is preferred if the individual being evaluated has previously received rabies immunization.

TABLE 15.16 Laboratory Diagnosis of Congenital and Neonatal Viral Infections

Virus	Recommended testing
Cytomegalovirus	NAAT or culture of urine and/or saliva during first 2 weeks of life
Herpes simplex	NAAT or culture of a vesicle, CSF, blood (plasma, serum, or whole blood). Conjunctiva, nasopharynx, oropharynx, urine, and rectum/stool may also be tested
Human immunodeficiency virus (HIV)	NAAT for HIV RNA on plasma or DNA on whole blood
Rubella	IgM antibody assay of serum or plasma, NAAT or culture of urine, oropharynx, blood, stool, CSF. Amniotic fluid and products of conception can also be tested
Parvovirus B19	IgM antibody assay of serum or plasma, NAAT of plasma or serum
Hepatitis B	Hepatitis B surface antigen test on serum or plasma
Varicella-zoster virus	NAAT, culture, or FA stain on vesicle, CSF, or blood. NAAT on amniotic fluid
Enteroviruses	NAAT on plasma or serum, CSF, nasopharyngeal or oropharyngeal swab, stool, urine
Hepatitis C	NAAT on plasma or serum on two occasions between 2 and 6 months of age or HCV antibody assay at age ≥15 months of age

CSF, cerebrospinal fluid; FA, fluorescent antibody; Ig, immunoglobulin; NAAT, nucleic acid amplification assay.

TABLE 15.17 Laboratory Diagnosis of Human Immunodeficiency and Other Retrovirus Infections

Indication	Test
Routine diagnosis	ELISA for HIV antibodies ^a
Confirmation of a positive ELISA	Samples that are reactive on the screening HIV antibody or combined HIV antigen–antibody assay should be tested with a confirmatory antibody test that differentiates HIV-1 and HIV-2 antibodies. ^b Patients who are positive with this assay should have a second sample tested for HIV RNA. Rare patients who are reactive on the screening test and the confirmatory HIV-1/HIV-2 antibody assay but negative for HIV RNA should have additional testing performed under the direction of an HIV specialist. This testing might include a repeat of the screening assay, an HIV western blot, or an HIV DNA PCR assay. Patients who are negative with the confirmatory HIV-1/HIV-2 antibody assay should have an HIV RNA assay performed. Patients who are reactive on the screening assay, negative on the confirmatory HIV-1/HIV-2 antibody assay, and positive for HIV RNA are presumed to have recent infection and should be referred immediately to an HIV specialist. ⁸
Blood donor screening	ELISA for antibodies to HIV-1 and -2, HIV RNA assay
Infant born to infected mother	HIV RNA or DNA assay at 14–21 days of age, 1–2 months, and 4–6 months ^c
Acute antiretroviral syndrome	HIV RNA assay
Prognosis	Quantitative HIV RNA assay
Response to therapy	Quantitative HIV RNA assay
Resistance to antiretroviral drugs	Genotypic assay based on nucleotide sequencing of the relevant genes, or phenotypic assay based on inserting relevant genes from the patient's HIV strain into a laboratory vector
Diagnosis of HIV-2 infection	ELISA for HIV-2 antibodies ^d
Monitoring of HIV-2 infection	HIV-2 RNA assay ^e
Diagnosis of HTLV-1 or -2 infection	HTLV-1 and 2 antibody ELISA assays
Confirmation of HTLV-1 or -2 infection	HTLV-1 and -2 western blot, line immunoassay or immunofluorescent antibody assay ^e

ELISA, enzyme-linked immunosorbent assay; HIV, human immunodeficiency virus; HTLV, human T-cell lymphoma or leukemia virus; PCR, polymerase chain reaction.

^aMost FDA licensed tests detect antibodies to both HIV-1 and -2. Third-generation antibody assays are preferred because they detect immunoglobulin M (IgM) as well as IgG antibodies, and thus become positive earlier after infection than assays that detect only IgG antibodies. An alternative approach is to use a fourth-generation test that measures HIV p24 antigen in addition to HIV antibodies.

^bA licensed rapid HIV antibody test approved by the Food and Drug Administration (FDA) is now available that differentiates HIV-1 and HIV-2 antibodies.

^cDNA PCR may be preferred while the infant is on prophylactic antiretroviral treatment because of the possibility that antiretroviral therapy may make HIV RNA undetectable.

^dMost HIV antibody assays currently in use detect antibodies to both HIV-1 and HIV-2, but only one FDA-licensed test differentiates between HIV-1 and HIV-2 antibodies.

^eAvailable only in selected reference laboratories.

TABLE 15.18 Laboratory Diagnosis of Tropical and Other Geographically Localized Viral Infections

Virus or syndrome	Location	Preferred tests
Sin nombre virus	Western United States	Virus-specific IgM antibody assay, NAAT
Other hantaviruses	Asia, Europe	Virus-specific IgM antibody assay, NAAT
Colorado tick fever	Western United States	Virus-specific IgM antibody assay, NAAT
Dengue fever	Asia, Central and South America	Virus-specific IgM antibody assay, NAAT
Filoviruses (Ebola and Marburg viruses)	Central Africa	Virus-specific IgM antibody assay, NAAT
Arenaviruses (e.g., Lassa, Junin, many others)	West Africa (Lassa fever), South American (Junin)	Virus-specific IgM antibody assay, NAAT, culture
Hendra and Nipah viruses	Australia, Malaysia, Bangladesh, India	Virus-specific IgM antibody assay, NAAT
Yellow fever	Central Africa, Amazon region	Virus-specific IgM antibody assay, NAAT
Crimean-Congo hemorrhagic fever and other bunyavirus infections	Asia, Africa, Europe	Virus-specific IgM antibody assay, antigen-capture ELISA, culture, NAAT
Rift Valley fever	East Africa	Virus-specific IgM antibody assay, antigen-capture ELISA, culture, NAAT, culture
Chikungunya and other alphavirus infections (O'nyong nyong, sindbis, Mayaro, Ross River)	Africa, India, Central and South America, Europe, Australia (Ross River)	Virus-specific IgM antibody assay, culture, NAAT

ELISA, enzyme-linked immunosorbent assay; IgM, immunoglobulin M; NAAT, nucleic acid amplification test.

of all of these amplification strategies is that no prior knowledge regarding the nature of the sequences to be amplified is required because it is unknown what type of virus may be present.

For sequence-based detection technologies, a key step is the computational analysis required to identify a sequence as viral in nature. In early efforts, only a few sequences were generated and thus analysis could easily be done via commonly used web-interface software. With advances in sequencing capacity, the number of sequences generated from a sample increased initially to hundreds or thousands and now can easily surpass a million sequences or more. In order to efficiently analyze this volume of sequence data, automated high-throughput bioinformatics pipelines had to be developed. Although many variations on this theme exist, most computational pipelines utilize very similar overall strategies. Typically, sequence alignment software, such as BLAST, is used to compare the sequences generated from a sample to established public databases. Sequences with perfect or near-perfect alignments to known sequences (host, viral, bacterial, etc.) can then be categorized based on the identity of the reference sequence to which a given read aligned. Sequences derived from novel viruses are those that have only limited similarity to known viruses in the available databases. For more definitive characterization of the relatedness of these sequences to known viruses, phylogenetic methods are subsequently used.

As mentioned previously, a key driving factor in the advances in virus discovery has been the evolution of sequencing technology. For over 30 years, from its inception in the late 1970s until the late 2000s, Sanger dideoxy sequencing was the dominant sequencing technology in use, and all efforts to identify viruses using sequencing-based strategies relied on this technology. At its highest throughput, automated 96-capillary Sanger sequencing could generate up to approximately 100,000 bp of sequence in a single run. Starting in 2005, the first of the so-called Next Generation (NextGen) sequencing platforms was introduced.⁸⁷ These platforms dramatically increased the quantity of sequence that could be produced. For example, the Roche/454 platform in its initial format was capable of generating 100,000 reads of 100 bp length in a single run, or approximately 100-fold greater sequence than a run on the previous instrument standard, the ABI 3730. Over the next few years, this platform rapidly evolved such that by 2009, the Roche/454 platform could readily generate 1,000,000 reads that averaged 400 bp, or 400 megabases (MB) of sequence. Two other major NextGen sequencing platforms, Solexa (Illumina) and SOLiD (ABI), also emerged during this time (reviewed in reference 86). Both of these platforms generate more reads than Roche/454, but of shorter length (up to 125 bp for Illumina, up to 75 for SOLiD). At the current time, these platforms are capable of generating on the order of 100 gigabases (GB) of sequence in a single run. It is the unprecedented growth in sequencing capacity offered by these new platforms that has transformed the process of virus discovery.

Novel Virus Discovery Strategies (2000–2010)

Random Arbitrarily Primed PCR

The 2001 discovery of human metapneumovirus relied on differential display of amplicons generated by a sequence-independent PCR amplification strategy.¹³⁹ An unknown virus was passaged in tertiary monkey kidney cells from respiratory

secretions of multiple children with respiratory tract infections. From nucleic acids purified from one such culture, a defined set of random, arbitrary primers was hybridized under low stringency to amplify nucleic acids from the culture and an uninfected control. Comparison of the resulting gel electrophoresis patterns yielded unique bands present only in the infected sample. These bands were selectively purified from the gel, sequenced, and found to share only limited sequence identity to avian pneumoviruses. Cultured virus was used to infect cynomolgus macaques, several of which developed mild respiratory symptoms and replicated virus as measured by RT-PCR, thus fulfilling Koch's postulates. Serologic analysis demonstrated that the virus is commonly acquired in childhood, with the majority of adults being seropositive. The human metapneumovirus is now established as one of the leading causes of viral respiratory infection.

DNase-SISPA

In 2001, Allander et al.² described DNase-SISPA (sequence-independent single primer amplification), a key virus discovery methodology that would be used to identify numerous novel viruses in the following years. Importantly, specific enrichment for capsid-protected viral nucleic acids in the specimen was carried out prior to nucleic acid extraction, using a combination of ultracentrifugation to pellet virions followed by treatment with DNase to degrade any free nucleic acids, presumably derived primarily from the host. RNA and DNA were independently extracted and analyzed in parallel. RNA was converted to double-stranded cDNA and then treated exactly as the extracted DNA. DNA was digested by restriction enzymes, a common linker was ligated to both ends of the double-stranded DNA fragments, and then the DNA was PCR amplified using a single common linker primer. Amplification products were visualized by gel electrophoresis, and individual bands were recovered from the gel, cloned, and sequenced using standard Sanger sequencing technology. In this proof of principle study, two novel bovine parvoviruses were identified in commercial bovine serum.

Random PCR Amplification-DNA Microarray Hybridization or "Virus Chip"

With the advent of DNA microarrays in the early 1990s, it rapidly became clear that the inherently parallel nature of microarrays could be utilized for massively parallel viral detection. Conceptually, the presence of a virus in a sample could be deduced from the pattern of hybridization to virus-derived oligonucleotide sequences on the microarray or so-called virus chip. The spectrum of viruses that could be detected in a single microarray hybridization was limited in theory only by the availability of viral sequences that could be included in a given microarray. The first broad-range viral detection microarray, which contained ~1,600 oligonucleotides capable of detecting ~140 viruses from all virus families with members known to cause respiratory disease, was described in 2002.¹⁴⁵ Critically, the most highly conserved 70-mer regions from these viruses were incorporated into the microarray to maximize the probability of detecting not only known viruses but also unsequenced or novel viruses by cross-hybridization to these highly conserved elements. The resulting pan-viral microarray is shown in Figure 15.12. The ability of the microarray

FIGURE 15.12. Pan-viral microarray used for virus discovery. (Wang D, Coscoy L, Zylberberg M, et al. Microarray-based detection and genotyping of viral pathogens. *Proc Natl Acad Sci U S A* 2002;99:15687–15692.)

to detect known viruses was validated using a series of known respiratory viruses grown in cell culture. To demonstrate the feasibility of detecting unknown viruses, multiple unsequenced strains of rhinoviruses grown in culture were hybridized to the microarray. Based on hybridization to many rhinovirus-derived sequences, these viruses could clearly be classified as rhinoviruses. Furthermore, to demonstrate that the method could be applied to human clinical samples and not just to cultured viruses, random PCR amplification of nucleic acids extracted directly from human respiratory specimens was employed. In this strategy, a single primer composed of a fixed linker region at the 5' end and five or more totally degenerate positions at the 3' end is the critical reagent.^{7,34} The degenerate 3' end can theoretically hybridize at any position on any DNA template, and when two primers hybridize to complementary strands in close proximity, the subsequent thermocycling generates an amplicon. In this fashion, all nucleic acids in a sample can be amplified at random. Microarray hybridization of randomly amplified nucleic acids extracted from the clinical specimens enabled detection of diverse known human respiratory viruses.

The first application of this approach to identify a novel virus occurred during the SARS outbreak of 2003.^{72,146} A second-generation pan-viral DNA microarray that contained ~11,000 70-mers derived from every fully sequenced viral genome in GenBank at the time was used to analyze an unknown virus cultured in Vero cells from the respiratory swab of a SARS patient. Random PCR followed by hybridization to the microarray yielded a hybridization pattern consistent with the presence of a divergent member of the family *Coronaviridae*; only a limited number of coronavirus-derived probes had high signal intensity. In order to rapidly sequence portions of the viral genome, fragments of the unknown virus that were bound to various 70-mers on the microarray were physically recovered, cloned, and sequenced.¹⁴⁶ These sequences shared only 33% identity to murine hepatitis virus, a murine coronavirus, definitively demonstrating that SARS was highly divergent from all previously described viruses.

VIDISCA

The discovery of human coronavirus NL63 in 2004 relied on VIDISCA (*Virus Discovery cDNA-AFLP* [amplified fragment length polymorphism]), a variant of the DNase-SISPA strategy¹⁴⁰ in combination with classic viral culture. From a 7-month-old child with bronchiolitis, cytopathic effect was detected following culture in tertiary monkey kidney cells. Material from those cultures was further passaged into LLC-MK2 cells. To identify the virus, supernatants from infected and uninfected cells were generated and subjected to VIDISCA. In this protocol, the initial steps were essentially identical to DNase-SISPA: ultracentrifugation, DNase treatment, nucleic acid purification, restriction endonuclease digestion, linker ligation, and PCR amplification. At this stage, a second set of PCR reactions was performed using all pairwise combinations of four PCR primers; each primer used contained one additional nucleotide (A, T, G, or C) appended to the 3' end of the linker primer used in the first round of PCR. Thus, 16 PCR reactions were performed with the goal of identifying specific bands present only in the infected cell culture and absent from the uninfected control. This process reduces the complexity of the banding pattern during gel electrophoresis compared to standard DNase-SISPA as each reaction should contain only one-sixteenth of the amplicons. In this instance, 16 bands unique to the infected sample were cloned, and 13 were determined to have only limited sequence similarity to known coronaviruses. Analysis of the complete genome of coronavirus NL63 determined that it shares 65% nucleotide identity to its closest relative, coronavirus 229E. Follow-up epidemiologic studies have defined an association of coronavirus-NL63 with croup.¹⁴¹

Rolling Circle Amplification/Restriction Digest/Gel Electrophoresis

The methods described previously have all utilized sequence-independent PCR amplification. An alternative non-PCR-based, sequence-independent amplification strategy relies on isothermal amplification using phi29 polymerase with random primers. This amplification strategy, also referred to variously as *rolling circle amplification*, *multiple displacement amplification*, and *whole genome amplification*, takes advantage of the highly processive nature of phi29 polymerase (greater than 70,000 average nucleotide extension) and its strand displacement

activity, which can lead to branching and thereby exponential amplification. When incubated with phi29 polymerase and random primers, small circular DNA viruses can be amplified by a factor of 10^4 . The products of this amplification, long double-stranded linear concatemers of viral genome monomers, can then be digested by restriction enzymes and visualized by gel electrophoresis. Bands can then be cloned and sequenced. In demonstrating proof of principle, Rector et al.¹¹² described the detection of a bovine papillomavirus from tissue. Subsequently, this approach would be used to identify the novel human polyomavirus 6.¹²⁰

Random PCR-Sanger High-Throughput Sequencing

The discovery of human bocavirus was the first example where PCR products from randomly amplified clinical material were sequenced en masse³; prior examples of sequencing-based discovery described previously relied on gel purification of specific individual target bands. In this study, respiratory secretions from multiple patients with unexplained respiratory illness were pooled, ultracentrifuged to concentrate viral particles, and DNase-treated to enrich for capsid-protected sequences. Following nucleic acid extraction, random PCR amplification, and size selection of 600- to 1,500-bp amplicons for cloning, 384 clones were sequenced using standard Sanger technology. Sequences with limited amino acid similarity to known parvoviruses were detected. Phylogenetic analysis demonstrated that this novel genome was a previously uncharacterized species of the genus *Bocavirus*. This experimental strategy would be used in many subsequent instances to identify novel viruses. With the evolution of NextGen sequencing platforms, many laboratories subsequently adapted their protocols to utilize NextGen sequencing technologies in place of the traditional Sanger sequencing. Multiple examples of viruses discovered by random PCR-NextGen sequencing will be described in the following sections.

NextGen High-Throughput Sequencing of a cDNA Library

The identification of Merkel cell polyomavirus in Merkel carcinomas was the first instance of the use of a NextGen sequencing platform (Roche/454 FLX platform) to discover a novel virus.²⁹ The experimental strategy, termed *digital transcriptome subtraction*, entailed sequencing of mRNA isolated from tumor tissue and subsequent computational subtraction of host sequences followed by alignment of the remaining sequences. Proof of concept for this type of strategy was first demonstrated in 2002, wherein an expressed sequence tag (EST) library derived from HeLa cells was subjected to computational subtraction of human sequences.¹⁴⁸ Among the remaining ESTs that did not match to any human sequences were human papillomavirus-18 sequences, which were known to be present in HeLa cells. In the Merkel carcinoma study, a total of four tumor samples were pooled and ~382,000 high-quality sequence reads were generated; from the data, one sequence possessed detectable sequence similarity to the T antigen of known polyomaviruses. The complete genome sequence of the novel virus, designated Merkel polyomavirus, was obtained, and phylogenetic analysis demonstrated that it was a highly divergent polyomavirus. Southern blotting determined that Merkel polyomavirus DNA was clonally integrated in a number of Merkel tumors. Multiple subsequent prevalence studies have determined that ~80%

of Merkel carcinoma tissues contain Merkel polyomavirus. This landmark study demonstrated the increased sensitivity achievable by deep sequencing with NextGen platforms as compared to previous efforts, wherein a single sequence of a novel virus (out of >380,000 total sequences sampled) could be detected. Moreover, no steps were taken to enrich the ratio of virus to host.

NextGen High-Throughput Sequencing of Small RNAs

Two studies demonstrated the feasibility of identifying novel viruses by sequencing and assembly of small RNAs.^{71,153} Following the discovery of RNA interference (RNAi), it became clear that RNAi has an antiviral function in plants and lower eukaryotic organisms; as a consequence, viral RNA sequences are cleaved to small RNAs ranging in size from ~21 to 25 nt. The presence of these small RNAs could readily be detected by gel-purifying small RNAs, using NextGen platforms to sequence the small RNAs. From these sequences, the application of assembly algorithms to reconstitute larger RNA fragments yielded contigs that could be clearly recognized as viral in nature. In plant experiments designed to analyze the effect of known sweet potato viruses on RNAi, previously undescribed badnaviruses and mastreviruses were detected by assembly of small RNAs.⁷¹ Similarly, analysis of small RNA sequencing data from *Drosophila* cell lines demonstrated that multiple novel viruses, including members of *Nodaviridae*, *Titiviridae*, *Birnaviridae*, and *Tetraviridae*, could be identified in this fashion.¹⁵³

Summary of Pathogen Discovery Methods

The methods described for virus discovery in the preceding paragraphs share a common end goal, albeit with multiple variations, namely, to identify nucleic acid sequences derived from viruses present in a sample of interest. The overall process can be dissected into distinct component modules, which in general can be mixed and matched, as illustrated in Figure 15.13. For a given specimen, different methods of processing the initial sample can be applied, different types of nucleic acid can be isolated, different sequence-independent amplification strategies can be used, and, ultimately, a range of technologies can be used as the readout. New combinations of these components continue to evolve.

Representative Novel Human Viruses Discovered (2000–2010)

Parvovirus 4

Screening of human plasma from patients with febrile illness by DNase-SISPA led to the discovery of sequences with only limited identity to known members of the family *Parvoviridae* in 2005.⁵⁸ The genome of a novel parvovirus, parvovirus 4, was sequenced. It has been detected to date in blood, bone marrow, and lymphoid tissue from patients with either HCV or HIV/acquired immunodeficiency syndrome (AIDS), in plasma of kidney transplant patients, and in CSF of encephalitis patients. The virus is believed to be parenterally transmitted based on the observation of high detection rates in hemophiliacs and injection drug users, although additional routes of transmission may also exist.

Anelloviruses

TT virus, the prototype anellovirus, was discovered in 1997 using representational difference analysis on human serum⁹⁵

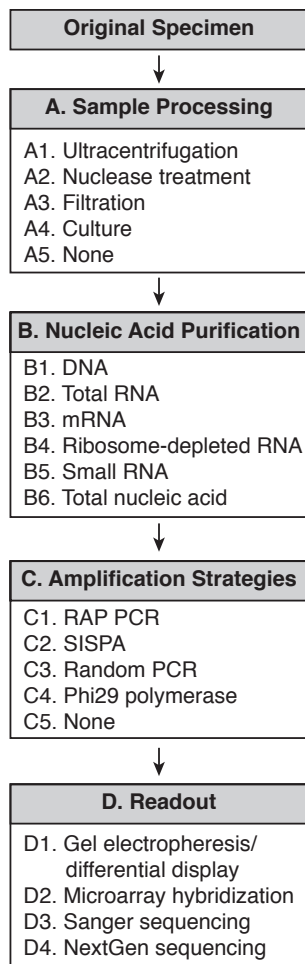

FIGURE 15.13. Pathogen discovery methods. Recently developed sequence-based pathogen discovery methods all fundamentally follow a similar overall scheme. A clinical specimen of interest is collected. **A:** If desired, samples can be manipulated to increase the ratio of virus to host by various methods. **B:** Nucleic acid species of interest is isolated. **C:** In cases where the quantity of purified nucleic acid is limiting, random sequencing-independent amplification is applied. **D:** A readout method is selected. For example, the identification of human bocavirus used the sequence of steps A1-A2-B1-C3-D3. The identification of Merkel polyomavirus used the sequence A5-B3-C5-D4.

from a transfusion-associated hepatitis patient. Since its discovery, TT virus and TT-related viruses have been found at high frequencies in a variety of human specimens, including respiratory secretions, stool, and serum. There is currently no known disease association for any of the anelloviruses. Two studies in 2005 described the presence of novel anelloviruses in human blood.^{9,58} In one study using DNase-SISPA to analyze serum from patients with febrile illness, two novel anelloviruses, SA1 and SA2, were identified that shared only 32% to 35% similarity to TT virus.⁵⁸ In the other study, plasma from healthy donors was enriched for virions by centrifugation through a cesium chloride (CsCl) step gradient. The fractions expected to contain known DNA viruses (1.2 to 1.5 g/mL density) were collected, DNase treated, and then extracted. Two amplification strategies were then used: (a) shearing followed by linker

ligation and sequence-independent PCR (as in DNase-SISPA) and (b) sequence-independent amplification using phi29 polymerase. In both instances, shotgun libraries were constructed and then sequenced. In this study, seven sequences with limited similarity to anelloviruses were detected. Since these studies, novel anelloviruses have been detected in numerous studies.^{30,143}

Novel Bocaviruses

Following the discovery of human bocavirus in respiratory secretions, a second novel bocavirus, named human bocavirus 2, was discovered by two independent groups using similar Sanger sequencing-based screening of stool samples of patients with acute flaccid paralysis⁶² and acute gastroenteritis.⁵ In the latter study, human bocavirus 2 prevalence of 17% in diarrhea cases was described, as was a statistically significant association between infection with human bocavirus 2 and acute gastroenteritis; however, in another study, no association was detected.⁶³ During efforts to describe the prevalence of human bocavirus and bocavirus 2 in human stools using consensus PCR, two additional human bocaviruses, human bocavirus 3⁵ and human bocavirus 4,⁶³ were discovered.

KI Polyomavirus

Using Sanger sequencing of pooled respiratory secretions physically enriched for virions, KI polyomavirus (KIV), a novel member of the family *Polyomaviridae*, was discovered in 2007.⁴ From the sequences generated, one 363-bp read possessed limited sequence similarity to the simian virus 40 (SV40) VP1 protein. From this one fragment, the complete 5,040-bp circular genome was sequenced. KIV has been detected in respiratory secretions in populations around the world as well as in feces. Seroepidemiologic studies have determined that a high percentage of the general population has been previously infected by KIV.^{13,64,94}

WU Polyomavirus

Nearly simultaneously with the discovery of KIV, WU polyomavirus (WUV) was discovered by a similar strategy of high-throughput Sanger sequencing analysis of individual respiratory secretions.³⁸ From 384 clones that were sequenced from the nasopharyngeal aspirate of a child with pneumonia, six sequence reads that shared 35% to 50% amino acid identity to JC virus and SV40 were detected. The complete genome of 5,229 bp was sequenced, and based on phylogenetic analysis, WUV was found to be most closely related to KIV. To date, WUV has been detected primarily in respiratory secretions, but it has also been detected in a few instances in feces, blood (whole blood, plasma, and serum), CSF, and lymphoid tissue. As with KIV, infection by WUV appears to occur primarily in childhood, with ~90% of adult populations harboring antibodies to WUV.^{13,64,94}

Human Polyomaviruses 6 and 7

During efforts to clone genomes of Merkel polyomavirus using rolling circle amplification of DNA collected from skin swab samples, a 1.6-kb BamHI fragment of a novel polyomavirus was detected. Subsequently, the complete genome of a novel virus designated human polyomavirus 6 was sequenced.¹²⁰ Based on this sequence, screening of skin swabs using degenerate PCR primers designed from human polyomavirus 6 and WU polyomavirus

yielded an additional virus, human polyomavirus 7. Serologic analysis of 95 blood donors using recombinant VP1 capsid protein demonstrated 69% and 35% seropositivity for human polyomavirus 6 and human polyomavirus 7, respectively.¹²⁰

TSV Polyomavirus

Trichodysplasia spinulosa (TSV) is a rare skin disease that occurs exclusively in immunocompromised patients. It is characterized by the development of spicules and follicular papules primarily on the face. Multiple case reports included electron micrographs demonstrating the presence of clusters of ~40-nm viral particles consistent with viruses in the polyomavirus or papillomavirus families. In 2010, DNA from the spicules collected from a heart transplant recipient suffering symptoms of TSV was subjected to rolling circle amplification (RCA). Restriction analysis of the RCA product yielded specific bands, which upon cloning and sequencing yielded a novel polyomavirus genome of 5,232 bp.¹⁴² Quantitative PCR demonstrated that the virus was present at 2×10^5 copies per cell. Prevalence studies performed on plucked eyebrows from 69 immunocompromised renal transplant patients yielded 3 (4%) that were TSV positive. TSV polyomavirus has subsequently been detected in two urine samples from two additional patients.¹²¹

Human Polyomavirus 9

Human polyomavirus 9 was discovered using a degenerate PCR amplification strategy from the serum of a kidney transplant patient.¹²¹ Sequencing of the complete genome demonstrated that human polyomavirus 9 was most closely related to the African green monkey lymphotropic virus. PCR-based screening of a cohort primarily composed of immunocompromised individuals yielded human polyomavirus 9 in three additional blood samples and one urine sample.

Asfarivirus-Like Virus

Random PCR-Roche/454 high-throughput sequencing was applied to human serum samples collected from patients suffering acute febrile illness and healthy controls in the Middle East. Multiple sequence fragments were detected in a total of four distinct serum samples that shared limited sequence identity (36% to 64% amino acid identity) to African swine fever virus proteins.⁸¹ African swine fever virus is the only known member of the family *Asfarviridae*, and the divergence between the detected sequences and known African swine fever viruses clearly demonstrate that the sequences represent one or more novel members of this family. No human infection with African swine fever virus has been reported. In addition, sequencing of raw sewage collected in Spain also yielded multiple sequence fragments that were most closely related to African swine fever virus. In total, 36 unique fragments were identified, including multiple fragments that shared sequence identity to genes specifically found only in African swine fever virus.

Novel Astroviruses

Astrovirus MLB1 was identified in the first metagenomic analysis of stools from patients with diarrhea.³⁰ Following filtration of diluted stool supernatant, RNA was extracted and randomly amplified. The amplicons were cloned and 384 clones were sequenced using standard Sanger sequencing. From the stool sample of a 3-year-old child from Australia with acute diarrhea, seven sequences with less than 68% amino acid identity to

known astroviruses were detected. The complete genome was sequenced, and phylogenetic analysis demonstrated it was a highly divergent astrovirus. The virus has been detected in stool samples of patients with and without diarrhea from the United States, Mexico, Hong Kong, India, and Nigeria.

Another novel astrovirus, astrovirus VA1, was discovered in stool samples collected from an unexplained outbreak of gastroenteritis in the United States by random PCR high-throughput sequencing. Parallel sequencing efforts using Sanger technology and the Roche/454 platform were used, in combination with conventional rapid amplification of cDNA ends (RACE) protocols, to sequence the entire genome.³² The robustness of NextGen platforms such as Roche/454 was demonstrated by the fact that the majority of the genome (a contig of 6,581 nt out of the complete genome of 6,586 nt) could be assembled from the initial Roche/454 data. Astrovirus VA1 shared only 61% amino acid identity to its closest relative, mink astrovirus. Real-time RT-PCR screening for astrovirus VA1 demonstrated that astrovirus VA1 was present at high copy number in three out of the six available stool samples from the outbreak. These results raise the possibility that astrovirus VA1 may play a role in causing diarrhea. Viruses very closely related to astrovirus VA1 were subsequently detected in three stool samples from children in Nepal⁶¹ and a patient in the Netherlands with celiac disease.¹²⁴ Furthermore, Roche/454 sequencing of encephalitic brain tissue from a child suffering from X-linked agammaglobulinemia yielded a virus closely related to astrovirus VA1.¹⁰⁹ Additional consensus astrovirus RT-PCR screening of stool samples led to the discovery of three additional astroviruses in human stool specimens in two independent studies: astrovirus MLB2, astrovirus VA2/HMO-A, and astrovirus VA3/HMO-B.^{31,61}

Saffold Cardiovirus

Saffold virus, a novel member of the *Cardiovirus* genus, was discovered by DNase-SISPA analysis of an unknown virus cultured from a patient stool sample.⁵⁹ Saffold-like viruses were subsequently detected directly in a sample of human respiratory secretions using a pan-viral microarray approach¹⁶ as well as in human stool from patients with gastroenteritis by PCR screening.^{16,26} Serologic studies using neutralization assays have yielded seropositivity rates of 80% to 90% by adulthood, demonstrating that Saffold infection is a common occurrence.^{17,155}

Rhinovirus C

By a consensus PCR strategy, a novel clade of rhinoviruses was identified in patients with influenza-like illness.⁷⁴ The many known serotypes of rhinoviruses have traditionally been classified into two clades, rhinovirus A and rhinovirus B. With the discovery in numerous studies of a novel set of related rhinoviruses, a new clade, designated rhinovirus C, has been established.⁶⁶⁻⁷⁶ These viruses appear to be globally widespread and may contribute to 50% or more of rhinovirus infections. No member of the rhinovirus C clade has been successfully cultivated in the cell lines traditionally used for detection of rhinoviruses.

Cosavirus

Random PCR followed by Sanger sequencing led to the discovery of a novel picornavirus, cosavirus A1, from a stool sample of a child with nonpolio acute flaccid paralysis from Pakistan.⁶⁰ Phylogenetic analysis of the complete genome of 7,634 bp determined that it is most closely related to Seneca Valley virus

in the genus *Cardiovirus*. In this study, PCR screening identified an additional 34 cosavirus-positive samples in cases and in healthy controls that, based on phylogenetic analysis, were further classified into four distinct genetic groups (A through D). An independent study also using random PCR and Sanger sequencing led to the identification of a proposed genetic group E of cosavirus.⁵⁴

Klassevirus/Salivirus

The identification of the novel picornavirus human klassevirus,^{55,144} also known as salivirus,⁷⁹ by three independent groups in 2009 relied primarily on Roche/454 sequencing. This virus is most similar to members of the genus *Kobuvirus* and has been detected both in human stool specimens from the United States,^{44,55,79} Australia,⁵⁵ Nigeria, Tunisia, and Nepal⁷⁹ and in raw sewage from Spain.⁵⁵ These results demonstrate that klassevirus/salivirus is globally widespread. In one study, 2 of 751 stool samples were positive for klassevirus, with the two positive patients twin siblings.⁴⁴ One case-control study in a Nepalese cohort demonstrated a positive association with gastroenteritis ($p = 0.0056$).⁷⁹

Coronavirus HKU1

Degenerate PCR screening of respiratory secretions resulted in the discovery of human coronavirus HKU1.¹⁵² This virus has been detected in numerous studies from respiratory samples from patients around the world.

Lymphocytic Choriomeningitis Virus–Like Arenavirus

In one of the earliest applications of Roche/454 high-throughput sequencing to viral detection, an arenavirus was identified in multiple recipients of organs from a common donor.⁹⁹ In this case cluster, three organ recipients from the same donor died 4 to 6 weeks after transplantation. RNA was extracted from the CSF, serum, brain, kidney, and liver from two patients, pooled, and sequenced. From a total of 94,043 high-quality sequence reads, 14 had detectable sequence similarity to lymphocytic choriomeningitis virus (LCMV). Following PCR to sequence the complete genome of the virus, RT-PCR testing of multiple specimens from each of the three individuals revealed identical viral sequences in all three patients. Virus was isolated by culture in Vero E6 cells. Using antibodies against LCMV, viral antigen was detected in liver and kidney sections, and seroconversion was observed in one patient.

Lujo Virus

In 2008, a cluster of five cases of undiagnosed hemorrhagic fever was reported in South Africa with four fatalities. Random PCR-Roche/454 high-throughput sequencing was performed on RNA extracted from two postmortem liver biopsies and one serum sample. Analysis of the resulting ~300,000 sequences yielded nine fragments with limited sequence similarity to known arenaviruses.¹⁰ Upon sequencing of the complete genome, phylogenetic analysis demonstrated that the virus, named Lujo virus, was highly divergent from known arenaviruses. Specimens collected from all five patients were positive for Lujo virus by virus isolation using cell culture and by RT-PCR.¹⁰³

Xenotropic Murine Leukemia Virus–Related Virus

In 2006, a novel retrovirus closely related to xenotropic murine leukemia viruses, named xenotropic murine leukemia virus–

related virus (XMRV), was first identified by random PCR pan-viral DNA microarray analysis.¹³⁷ The samples analyzed were prostate tumor specimens, and presence of the virus was associated with a specific polymorphism of the *RNaseL* gene, a key component of the interferon-induced antiviral defense system. In further studies of prostate cancer specimens, XMRV was also detected in one instance¹¹⁹ but not in another.¹³¹ Subsequently, one study suggested an association between chronic fatigue syndrome and XMRV.⁸² This finding, however, has been contradicted by numerous studies that have failed to detect XMRV in chronic fatigue patients, including a large multicenter blinded study¹²³ and a study that retested patients previously identified to have the virus in the original study.⁶⁷ Furthermore, multiple studies have demonstrated that reagents often used in RT-PCR and other manipulations can be contaminated with XMRV-like sequences, raising the possibility that amplification artifacts and contamination contribute to some of the observations.¹³¹ Finally, one study demonstrated that XMRV likely arose via recombination between two murine retroviruses in the course of prostate tumor xenograft experiments, suggesting that this virus is an artifact of laboratory experimentation.¹⁰¹ These studies illustrate some of the potential challenges of defining the biological relevance of newly identified agents using primarily molecular approaches.

Prospects and Challenges for the Future

Advances in molecular methods have dramatically increased the rate at which viral genomes can be detected, resulting in our awareness of the existence of many more viral genomes than just a few years ago. For example, following the initial discoveries of BK and JC viruses by culture in 1971, there were no additional polyomaviruses of humans identified until 2007. Since then, a total of seven new polyomaviruses have been identified in humans, all by molecular methods. Parallel situations exist in many viral taxa, wherein geometric increases in the number of known members have been observed. With the continued growth in sequencing capacity, there is little doubt that many more viruses will be identified in the upcoming years. Recently, specific efforts to comprehensively catalog the spectrum of viruses present in humans have begun. One objective of the international Human Microbiome Project is to define the set of viruses present in different anatomic sites in a set of “healthy” adults. These and other similar efforts to define the “viromes” of humans, animals, plants, or environmental niches will undoubtedly uncover a tremendous diversity of new viral genomes. While our ability to identify viral nucleic acids and genomes has grown at an astounding rate, our ability to define the molecular properties and the biological relevance of these new agents has unfortunately lagged behind. In order to effectively study these new viruses, commensurate new developments in traditional virology must occur. For example, novel methods of virus culture must be developed in order to keep pace with the rate of discovery of new viral sequences, as the ability to propagate a virus in culture is, in many instances, the rate-limiting step in our ability to further characterize a virus and to define its pathogenicity. Many of the viruses being discovered today by sequencing-based molecular methods are unlikely to grow in the traditional cell lines utilized by virologists. As an example, the advent of differentiated primary respiratory epithelial cultures has opened new frontiers by enabling the culture of several newly identified respiratory viruses, such

as human bocavirus²⁵ and coronavirus HKU,¹⁰⁸ that have failed to grow previously in traditional respiratory tract–derived cell lines. Another area of great importance is the development of robust animal models for these new agents, which will be a critical part of efforts to define pathogenicity and disease causality. Finally, the criteria used for defining “pathogenicity” must also be revisited. While Koch’s postulates, the 100-plus-year-old gold standard for proof of disease causation, have served us well in the past, this era of molecular virus discovery necessitates an enhanced emphasis on the role of epidemiologic and seroepidemiologic approaches in defining disease associations.³³ Furthermore, more nuanced conceptions of microbially induced disease, such as disease as a consequence of imbalance or perturbation of host microbial populations, must also be considered. In summary, technology-driven advances in sequencing have led to a golden era of discovery of new viruses in the first decade of the 21st century. Hopefully, parallel advances in understanding the biology of these new agents will come to fruition in the next decades of the 21st century.

PERSPECTIVE

Diagnostic virology is at a critical point in its history. The field has matured, with detection of a selected group of viral pathogens emerging as an important component of clinical laboratory services at major medical centers. For example, the detection of respiratory viruses; diagnosis and monitoring of viral infections, especially CMV, EBV, and BK virus in immunocompromised patients; viral load and antiviral susceptibility testing for HIV, HCV, and HBV; and testing for HPV have all become mainstream diagnostic procedures. The methodology of diagnostic virology is evolving rapidly, with increasing conversion to molecular methods. The development of standardized commercial molecular tests that have passed through the review processes of the FDA has been relatively slow but is now beginning to gain momentum. At the same time, the process of virus discovery, described earlier, is dramatically expanding the vistas of medical virology. In the coming years, it may become necessary to detect many viruses other than those for which FDA-approved assays are under development. Relatively unbiased methods such as NextGen sequencing, currently being used mainly for virus discovery, will undoubtedly be evaluated in the clinical laboratory setting. In addition, new paradigms, including recognition and diagnosis of diseases that result from multiple microbial interactions as well as diseases that occur uniquely in an individual based on that individual’s genetic makeup, may require profound changes in the way in which diagnostic testing is performed. Assays to detect the presence of viruses may need to be combined with assays to evaluate biomarkers that provide information on how the host is reacting to the presence of the virus. Genetic markers may need to be evaluated to help define how an individual patient is likely to respond to viral infection. In addition, there is little doubt that unforeseen technological advances will drive the evolution of the field in directions that are currently impossible to predict.

DISCLOSURES

Dr. Storch serves on the medical advisory board of Roche Molecular Systems and has served as a consultant to Idaho Technology,

PrimeraDx, Abbott, and Diagnostic Hybrids. He has received an honorarium from GenProbe and Meridian. He is currently performing research funded by Luminex and Meridian. Dr. Wang has no disclosures.

Perspectives

Viruses in the family *Picornaviridae* have nonenveloped particles with a single-stranded RNA (ssRNA) genome of positive polarity. Among its many members are numerous important human and animal pathogens, such as poliovirus, hepatitis A virus, foot-and-mouth disease virus (FMDV), enterovirus 71,

and rhinovirus. The name of the virus family was intended to convey the small size of the viruses (pico, a small unit of measurement [10^{-12}]) and the type of nucleic acid that constitutes the viral genome (RNA).

Picornaviruses have played important roles in the development of modern virology. Foot-and-mouth disease virus was the first animal virus to be discovered, by Loeffler and Frosch in 1898.³⁰⁵ Poliovirus was isolated 10 years later,²⁸⁹ a discovery spurred by the emergence of epidemic poliomyelitis at the turn of the 20th century. The discovery in 1949 that poliovirus could be propagated in cultured cells led to studies of viral replication.¹³⁵ The plaque assay, an essential method for quantification of viral infectivity, was developed with poliovirus.¹³⁰ The first RNA-dependent RNA polymerase identified was that of mengovirus,²⁹ a picornavirus, and the synthesis of a precursor polyprotein from which viral proteins are derived by proteolytic processing was first identified in poliovirus-infected cells.⁴⁷⁷ The first infectious DNA clone of an animal RNA virus was that of poliovirus,⁴¹⁶ and the first three-dimensional structures of animal viruses determined by x-ray crystallography were those of poliovirus²²³ and rhinovirus.⁴³⁵ Poliovirus RNA was the first messenger RNA (mRNA) shown to lack a 5' cap structure.^{215,361} This observation was subsequently explained by the finding that the genome RNA of poliovirus and other picornaviruses is translated by internal ribosome binding,^{243,385} a process now known to occur on cellular mRNA.^{248,313}

Because they cause serious diseases, poliovirus and FMDV have been the best-studied picornaviruses. Research on poliovirus has produced two effective vaccines; it is likely that poliomyelitis will be eradicated from the globe in the near future. The World Health Organization (WHO) has established a goal of cessation of vaccination, at which time all poliovirus stocks must be destroyed. When this historic event takes place, all research on this virus will cease. Poliovirus is truly a virus with a brilliant past, but with no future.

CLASSIFICATION

The family *Picornaviridae* belongs to the order *Picornavirales* and comprises 12 genera (Table 16.1), which all contain viruses that infect vertebrates.²⁸⁰ Information on selected viruses is summarized below.

The genus *Aphthovirus* consists of four species: *Foot-and-mouth disease virus* (FMDV), *Bovine rhinitis A virus*, *Bovine rhinitis B virus*, and *Equine rhinitis A virus*. FMDV infects cloven-footed animals (e.g., cattle, goats, pigs, and sheep), primarily via the upper respiratory tract, and has been isolated from at least 70 species of mammals. Seven serotypes of FMDV have been identified; within each serotype are many subtypes. These viruses are highly labile and rapidly lose infectivity at pH values of less than 6.8.

There are two species within the genus *Cardiovirus*: *Encephalomyocarditis virus* and *Theilovirus*. The encephalomyocarditis viruses (which include strains known as encephalomyocarditis virus, Columbia SK virus, Maus Elberfeld virus, and Mengovirus) are murine viruses, which can also infect many other hosts, including humans, monkeys, pigs, elephants, and squirrels. The second species includes the Theiler's murine encephalomyelitis viruses and human Saffold viruses.

TABLE 16.1 Members of the Family *Picornaviridae*

Genus	Species
<i>Aphthovirus</i>	<i>Foot-and-mouth disease virus</i> <i>Equine rhinitis A virus</i> <i>Equine rhinitis B virus</i>
<i>Avihepatovirus</i>	<i>Duck hepatitis A virus</i>
<i>Cardiovirus</i>	<i>Encephalomyocarditis virus</i> <i>Theilovirus</i>
<i>Enterovirus</i>	<i>Bovine enterovirus</i> <i>Human enterovirus A (Coxsackievirus, enterovirus)</i> <i>Human enterovirus B (Coxsackievirus, echovirus, enterovirus)</i> <i>Human enterovirus C (poliovirus, Coxsackievirus, enterovirus)</i> <i>Human enterovirus D (enterovirus)</i> <i>Porcine enterovirus B</i> <i>Simian enterovirus A</i> <i>Human rhinovirus A</i> <i>Human rhinovirus B</i> <i>Human rhinovirus C</i>
<i>Erbovirus</i>	<i>Equine rhinitis B virus</i>
<i>Hepatovirus</i>	<i>Hepatitis A virus</i>
<i>Kobuvirus</i>	<i>Aichi virus</i> <i>Bovine kobuvirus</i>
<i>Parechovirus</i>	<i>Human parechovirus</i> <i>Ljungan virus</i>
<i>Sapelovirus</i>	<i>Porcine sapelovirus</i> <i>Simian sapelovirus</i> <i>Avian sapelovirus</i>
<i>Senecavirus</i>	<i>Seneca Valley virus</i>
<i>Tremovirus</i>	<i>Avian encephalomyelitis virus</i>
<i>Teschovirus</i>	<i>Porcine teschovirus</i>

There are 10 species in the *Enterovirus* genus: *Human enterovirus A, B, C, D*; *Simian enterovirus A*, *Bovine enterovirus*, *Porcine enterovirus B*, and *Human rhinovirus A, B, C*. Members of this genus include poliovirus (3 serotypes), Coxsackievirus (25 serotypes), echovirus (28 serotypes), human enterovirus (43 serotypes), and many nonhuman enteric viruses. Enteroviruses such as poliovirus (3 serotypes) and Coxsackievirus (25 serotypes) replicate in the alimentary tract and are resistant to low pH. The acid-labile rhinoviruses (so named because they replicate in the nasopharynx) are important agents of the common cold. There are 100 serotypes of *Human rhinovirus A and B*. Rhinoviruses may also replicate in the lower respiratory tract; the newly discovered *Human rhinovirus C* (49 types) have been associated with severe lower respiratory tract disease.³²⁷

The genus *Hepatovirus* contains a single species, the human pathogen *Hepatitis A virus* (one serotype). Virions are highly stable and resistant to acid pH and high temperatures (60°C for 10 min). The virus infects epithelial cells of the small intestine and hepatocytes.

The *Parechovirus* genus contains two species, *Human parechovirus* and *Ljungan virus*, a virus of rodents. Parechoviruses are etiologic agents of respiratory and gastrointestinal disease.

Proteins of parechoviruses are substantially diverged from those of other picornaviruses, with no greater than 30% amino acid identity.

The *Erbovirus* genus contains three types of *Equine rhinitis B virus*. These viruses cause upper respiratory tract disease in horses that is associated with viremia and fecal shedding of virus particles. The *Kobuvirus* genus contains two species: *Aichi virus*, which causes gastroenteritis in humans, and *Bovine kobuvirus*. The *Teschovirus* genus consists of 12 serotypes of *Porcine teschovirus*. Some strains can cause polioencephalitis in pigs, also called Teschen/Talfan disease or teschovirus encephalomyelitis. There are three species in the *Sapelovirus* genus: *Porcine sapelovirus*, *Simian sapelovirus*, and *Avian sapelovirus*. The sole species in the genus *Senecavirus* is *Seneca Valley virus*, found in pigs throughout the United States, but there is no known associated disease. It is currently in clinical trials to assess its value for treating human tumors.⁴⁴⁰ *Avian encephalomyelitis virus*, which causes the eponymous disease in young chickens, pheasants, quail, and turkeys, is the sole species in the genus *Tremovirus*.

A number of other related viruses may be members of the *Picornaviridae* but have not been approved as species by the International Committee on Taxonomy of Viruses (ICTV). These include human cosaviruses, identified in the stools of south Asian children,^{224,262} human klassevirus/salivirus,^{183,225,297} and many others.²⁸⁰

VIRION STRUCTURE

Physical Properties

Picornavirus virions are spherical, with a diameter of about 30 nm (Fig. 16.1). The particles are simple, consisting of a protein shell surrounding the naked RNA genome. The virus particles lack a lipid envelope, and their infectivity is insensitive to organic solvents. Cardioviruses, enteroviruses (except rhinoviruses), hepatoviruses, and parechoviruses are acid stable and retain infectivity at pH values of 3.0 and lower. In contrast, rhinoviruses and aphthoviruses are labile at pH values of less than 6.0. Differences in pH stability influence the sites of replication of the virus. For example, rhinoviruses and aphthoviruses replicate in the respiratory tract and need not be acid stable. Because they are acid labile, they cannot replicate in the alimentary tract. Cardioviruses, enteroviruses, hepatoviruses, and parechoviruses pass through the stomach to gain access to the intestine and, therefore, must be resistant to low pH. The structural basis for the acid lability of FMDV is partly understood (see *Entry into Cells*).

The buoyant densities of picornaviruses are quite different (Table 16.2). Cardioviruses and enteroviruses have a buoyant density of 1.34 g/mL, that of FMDV is 1.45 g/mL, and rhinoviruses have an intermediate value (1.40 g/mL). The reason for the difference lies in the permeability of the viral capsid to cesium. The capsid of poliovirus does not allow cesium to reach the RNA interior; thus, the virus bands at an abnormally light buoyant density.¹⁴⁶ In contrast, aphthovirus capsids contain pores that allow cesium to enter.¹ The rhinovirus capsid is permeable to cesium, but the presence of polyamines in the capsid interior limits the amount of cesium that can enter, which provides an explanation for the intermediate buoyant density value of these viruses.¹⁴⁶

Roberts, WHO Poliomyelitis Regional Reference Laboratory, Victorian Infectious Diseases Reference Laboratory, North Melbourne, Australia.)

TABLE 16.2 Physical Properties of Some Picornaviruses

Genus	pH stability	Virion buoyant density	Sedimentation coefficient
<i>Aphthovirus</i>	Labile, <6.8	1.43–1.45	142–146S
<i>Cardiovirus</i>	Stable, 3–9	1.33–1.34	160S
<i>Enterovirus</i>			
Enteroviruses	Stable, 3–9	1.34	160S
Rhinoviruses	Labile, <6	1.40	160S
<i>Hepatovirus</i>	Stable	1.32–1.34	160S
<i>Parechovirus</i>	Stable	1.36	160S

Ratio of Particles to Infectious Viruses

The ratio of particles to infectious virus is determined by dividing the number of virus particles in a sample (determined by electron microscopy [EM] or spectrophotometric measurements) by the plaque titer, yielding the particle-to-plaque forming unit (pfu) ratio. This ratio is a measurement of the fraction of virus particles that can complete an infectious cycle. The particle-to-pfu ratio of poliovirus ranges from 30 to 1,000, and that of other picornaviruses is in the same range. The high particle-to-pfu ratio may be caused by the presence of lethal mutations in the viral genome. This explanation, however, probably does not apply to all picornaviruses; it has been shown that the infectivity of aphthovirus RNA approaches one infectious unit per molecule. An alternative explanation is that all viruses do not successfully complete an infectious cycle because they fail at one of several steps that must be completed, including attachment, entry, replication, and assembly.

High-Resolution Structure of the Virion

The capsids of picornaviruses are composed of four structural proteins: VP1, VP2, VP3, and VP4. The results of x-ray diffraction studies, EM observations, and biochemical studies of virus particles and their dissociation products led to the hypothesis that the picornavirus capsid contains 60 structural proteins arranged into an icosahedral lattice.⁴⁴¹ Our understanding of the structure of picornaviruses was substantially advanced in 1985 when the atomic structures of poliovirus type 1²²³ and human rhinovirus type 14⁴³⁵ were determined by x-ray crystallography. Since then, the high-resolution structures of many other picornaviruses have been determined.

The basic building block of the picornavirus capsid is the protomer, which contains one copy each of VP1, VP2, VP3, and VP4. The shell is formed by VP1 to VP3, and VP4 lies on its inner surface (Fig. 16.1). VP1, VP2, and VP3 have no sequence homology, yet all three proteins have the same topology: they form an eight-stranded, antiparallel β -barrel (also called a β -barrel jelly roll or a Swiss-roll β -barrel). This domain is a wedge-shaped structure made up of two antiparallel β -sheets. One β -sheet forms the wall of the wedge, and the second, which has a bend in the center, forms both a wall and the floor. The wedge shape facilitates the packing of structural units to form a dense, rigid protein shell. Packing of the β -barrel domains is strengthened by a network of protein–protein contacts on the interior of the capsid, particularly around the fivefold axes. This network, which is formed by the N-terminal extensions of VP1 to VP3 as well as VP4, is essential for the stability of the virion.

VP4 differs significantly from the other three proteins in that it has an extended conformation. This protein is similar in position and conformation to the NH₂-terminal sequences of VP1 and VP3 and functions as a detached NH₂-terminal extension of VP2 rather than an independent capsid protein.

The main structural differences among VP1, VP2, and VP3 lie in the loops that connect the β -strands and the N- and C-terminal sequences that extend from the β -barrel domain. These amino acid sequences give each picornavirus its distinct morphology and antigenicity. The C-termini are located on the surface of the virion, and the N-termini are on the interior, indicating that significant rearrangement of the P1 precursor occurs on proteolytic cleavage.

Resolution of the structures of poliovirus and rhinovirus revealed that the β -barrel domains are strikingly similar in structure to those of plant viruses such as southern bean mosaic virus and tomato bushy stunt virus. The capsid proteins of these viruses bear no sequence homology with those of the picornaviruses. It has since become apparent that similar protein topology is found in the capsid proteins of many plant, insect, and vertebrate positive-stranded RNA viruses as well as in the DNA-containing papovaviruses and adenoviruses. These findings suggest that either the polypeptides evolved from a common ancestor or that the β -barrel domain is one of the few ways to allow proteins to pack to form a sphere.

In some viruses, such as the parechoviruses, VP0, the precursor to VP2 + VP4, remains uncleaved, while in hepatitis A virus, VP4 is very small.

Surface of the Virion

Resolution of the structures of poliovirus and human rhinovirus revealed that the surfaces of these viruses have a corrugated topography; a prominent, star-shaped plateau (mesa) is found at the fivefold axis of symmetry, surrounded by a deep depression (canyon) and another protrusion at the threefold axis (Fig. 16.1). It was originally proposed that the canyon is the receptor-binding site—this hypothesis has been proved for a number of enteroviruses. Not all picornaviruses have canyons. The surface of cardioviruses bears a series of depressions, or “pits,” which are involved in receptor binding, while that of FMDV is much smoother. As will be discussed later, a flexible loop that projects from the capsid surface binds to the cellular receptor for FMDV.

Interior of the Virion

A network formed by the N-termini on the interior of the capsid contributes significantly to the stability of the virion.

At the fivefold axis of symmetry, the N-termini of five VP3 molecules form a cylindrically parallel β -sheet. This structure is surrounded by five three-stranded β -sheets formed by the N-termini of VP4 and VP1. The myristate group attached to the N-terminus of VP4 mediates the interaction between these two structures.⁹³ Interactions among pentamers are stabilized by a seven-stranded β -sheet, composed of four β -strands of the VP3 β -barrel and one strand from the N-terminus of VP1 that surround a two-stranded β -sheet made from the N-terminus of VP2 from a neighboring pentamer.¹³⁸

Poliovirus genomes containing an extra 1,500 nucleotides can be successfully packaged, indicating that the interior of the capsid is not fully occupied.⁹ It has been suggested that picornaviral capsids are stabilized by interactions with the RNA genome, based on findings with bean pod mottle virus, which is related to picornaviruses. In this virus, ordered RNA can be observed at the threefold axis, and packaging of viral RNA stabilizes subunit interactions.^{91,299} Several nucleotides have been tentatively identified in a similar location in the structures of P3/Sabin and rhinovirus type 14.^{25,138} In the atomic structure of poliovirus P2/Lansing, RNA bases have been observed stacking with conserved aromatic residues of VP4.²⁹⁴ The structure of *Seneca Valley virus* revealed the arrangement of the RNA within the capsid.⁵¹¹ Much of the nucleic acid contacts the inner surface of the capsid, particularly near the twofold axes under VP2. The RNA forms a shell that contacts both VP2 and VP4 and which could serve as a scaffold for capsid assembly or might contribute to virion stability.

Hydrophobic Pocket

Within the core of VP1, just beneath the canyon floor of many picornaviruses, is a hydrophobic tunnel or pocket (Fig. 16.2). Electron density observed in this area has been interpreted to be cell-derived lipids called “pocket factors.” In poliovirus types 1 and 3, the pocket is believed to contain sphingosine.¹³⁸ An unidentified lipid has been found in human rhinoviruses types 1A and 16, a C16 fatty acid has been modeled in the pocket of coxsackievirus B3,^{194,271,348} coxsackievirus A21 is believed to carry myristic acid,⁵³⁵ and bovine enterovirus contains a mixture of palmitic and myristic acid.⁴⁶⁴ In the enterovirus 71 virion, the pocket factor is partly exposed on the floor of the canyon.⁴⁰³ In contrast, the pocket of human rhinovirus type 14 is empty.²⁵ The results of introducing amino acid changes in the pocket of rhinovirus 16 suggest that the hydrophobic pocket, and not the pocket factor, is important for maintaining capsid dynamics.²⁶⁵

The hydrophobic pocket is also the binding site for anti-picornavirus drugs such as the WIN compounds produced by Sterling-Winthrop⁴⁶² as well as similar molecules produced by Janssen Pharmaceuticals (Titusville, NJ)^{19,104} (Fig. 16.2). Some of these drugs have been evaluated in clinical trials, such as pleconaril for treatment of common colds caused by rhinoviruses³⁹² and for enteroviral sepsis syndrome.³⁵⁶ These hydrophobic, sausage-shaped compounds bind tightly in the hydrophobic tunnel, displacing any lipid that is present, inhibiting either binding or uncoating. Drug-dependent mutants of poliovirus spontaneously lose infectivity at 37°C, probably because they do not contain lipid in the pocket.³⁴⁷

Myristate

Myristic acid (*n*-tetradecanoic acid) is covalently linked to glycine at the amino terminus of VP4 of most picornaviruses.⁹³

This fatty acid is an integral part of the viral capsid. The N-termini of VP3 intertwine around the fivefold axis to form a twisted tube of parallel β -structure.²²³ The five myristyl groups extend from the N-termini of VP4 and cradle the twisted tube formed by VP3.⁹³ The myristyl groups interact with amino acid side chains of VP4 and VP3. Mutagenesis of VP4 has revealed a role for myristic acid modification in virus assembly and in the stability of the capsid.^{20,314–316,344}

Neutralizing Antigenic Sites

Viral serotype is determined by the connecting loops and C-termini of the capsid proteins that decorate the outer surface of the virion. These contain the major neutralization antigenic sites of the virus, the amino acid sequences that are recognized by antibodies that block viral infectivity. Such sites are defined by mutations that confer resistance to neutralization with monoclonal antibodies directed against the viral capsid.^{334,335,458} Human sera contain antibodies directed against poliovirus antigenic sites identified in mice.⁴²³

The large area of contact of the poliovirus receptor (PVR) CD155 on the virion surface, compared with other picornavirus–receptor interactions, might provide a clue to why there are many rhinovirus serotypes but only three serotypes of poliovirus.²⁰⁹ This large interaction area could limit the viability of antibody-escape mutants because they would also compromise their ability to bind CD155.

The capsids of rhinovirus, poliovirus, and other picornaviruses are dynamic, leading to transient display of the buried N-termini of VP1.^{246,266,298,411,432,446} Antibodies to this sequence of VP1 neutralize viral infectivity.

GENOME STRUCTURE AND ORGANIZATION

General Features

The genome of picornaviruses is a single positive-stranded RNA molecule (Fig. 16.3). The viral RNA is infectious because it is translated on entry into the cell to produce all the viral proteins required for viral replication. Picornavirus genomic RNA is unique because it is covalently linked at the 5′ end to a protein called VPg (virion protein, genome linked).^{142,293} VPg is covalently joined to the 5′-uridylylate moiety of the viral RNA by an O4-(5′-uridylyl)-tyrosine linkage. The tyrosine that is linked to the viral RNA is always the third amino acid from the N-terminus. VPg of different picornaviruses varies in length from 22 to 24 amino acid residues and is encoded by a single viral gene, except in the genome of FMDV, which encodes three VPg genes.¹⁴⁵ VPg is not required for infectivity of poliovirus RNA; if it is removed from viral RNA by treatment with proteinase, the specific infectivity of the viral RNA is not reduced. VPg is not found on viral mRNA that is associated with cellular ribosomes and undergoing translation; these mRNA contain only uridine 5′-phosphate (pU) at their 5′ ends. Poliovirus mRNA differs from virion RNA only by the lack of VPg.^{363,389} VPg is removed from virion RNA by a host protein called *unlinking enzyme*.¹² It is not known whether removal of VPg is a prerequisite for association with ribosomes or is a result of that association. Although VPg-linked RNA can be translated in cell-free extracts, it is possible that VPg is rapidly cleaved from the RNA such that only RNA lacking VPg are translated.^{169,338,514} VPg is present on nascent RNA

FIGURE 16.2. The hydrophobic pocket in the picornavirus capsid. **A:** Cellular lipid bound in the hydrophobic pocket of poliovirus type 1. Side view of a protomer, consisting of one copy each of VP1, VP2, VP3, and VP4. RNA is below, and the fivefold axis of symmetry is at the upper right. Gray spheres represent what is believed to be a molecule of sphingosine bound in the hydrophobic pocket. The lipid is just below the canyon floor. **B:** Drug bound in the poliovirus pocket. R78206, a WIN-like compound, bound in the poliovirus capsid. The bound drug is the small yellow molecule at the base of the canyon. The drug appears to be exposed on the surface but is actually in the hydrophobic pocket. The capsid model is shown in a radial depth-cued representation, in which atoms are colored according to whether they are near the center of the virus (blue) or far from the center (white). Residues at the bottom of the canyon are dark because they are at a position of low radius. The bound drug is not depth cued. **C:** WIN52084 bound in the hydrophobic pocket. These drugs displace the lipid from the pocket, thereby blocking infectivity.

chains of the replicative intermediate RNA and on negative-stranded RNA, which has led to the suggestion that VPg is a primer for poliovirus RNA synthesis.^{362,389} The role of VPg in viral RNA synthesis is discussed in subsequent sections.

Nucleotide sequence analysis of many picornavirus RNAs has revealed a common organizational pattern (Fig. 16.3). The genomes vary in length from 7 to 8.8 kb. The 5′-noncoding regions of picornaviruses are long (0.5 to 1.5 kb) and highly structured. This region of the genome contains sequences that

control genome replication and translation. The 5′-noncoding region contains the internal ribosome entry site (IRES) that directs translation of the mRNA by internal ribosome binding. The 5′-untranslated regions of aphthoviruses, cardioviruses, and erboviruses contain a poly(C) tract that varies in length among different virus strains (80 to 250 nucleotides in cardioviruses, 40 to 400 nucleotides in aphthoviruses). Among cardioviruses, longer poly(C) length is associated with higher virulence in animals.^{129,198}

FIGURE 16.3. Organization of a picornavirus genome. **Top:** Schematic of the viral RNA genome, with the genome-linked protein VPg at the 5' end, the 5' untranslated region containing the IRES, the protein coding region, the 3' untranslated region containing a pseudoknot, and the poly(A) tail. L is a leader protein encoded in the genomes of erboviruses, cardioviruses, and aphthoviruses but not other picornaviruses. Coding regions for the viral proteins are indicated. **Bottom:** Processing pattern of picornavirus polyprotein. Some genomes encode multiple copies of protein coding regions, e.g., there are three VPgs in the FMDV genome, two 2A motifs in Ljungan virus, and three 2A motifs in the duck hepatitis A virus genome.

The 3'-noncoding region of picornaviruses is short, ranging in length from 40 to 330 nucleotides. This region may also contain a secondary structure, a pseudoknot, that has been implicated in controlling viral RNA synthesis.²⁴¹ The entire 3'-noncoding region of poliovirus and rhinovirus is not required for infectivity, however.^{77,489} Both virion RNA and mRNA contain a 3' stretch of poly(A).⁵⁴¹ Negative-stranded RNA contains a 5' stretch of poly(U), which is copied to form poly(A) of the positive strand.⁵⁴² The average length of the poly(A) tail varies from 35 nucleotides in encephalomyocarditis virus to 100 nucleotides in aphthoviruses.⁵ Viral RNA from which the poly(A) tract is removed is noninfectious.⁴⁶⁹

The results of biochemical studies of poliovirus-infected cells had predicted the presence of a single, long, open reading frame (ORF) on the viral RNA that is processed to form individual viral proteins.⁴⁷⁷ This hypothesis was proved when the nucleotide sequence of the poliovirus genome was determined, which revealed that the viral RNA encodes a single ORF.^{276,415} A similar strategy for viral gene expression occurs during the replication of all picornaviruses. The polyprotein is cleaved during translation, so that the full-length product is not observed. Cleavage is carried out by virus-encoded proteinases to yield 11 to 15 final cleavage products. Some of the uncleaved precursors also have functions during replication.

To unify the nomenclature of picornavirus proteins, the polyprotein has been divided into three regions: P1, P2, and P3 (Fig. 16.3). The genomes of some picornaviruses encode a leader (L) protein before the P1 region. The P1 region encodes the viral capsid proteins, whereas the P2 and P3 regions encode proteins involved in protein processing (2A^{pro}, 3C^{pro}, 3CD^{pro}) and genome replication (2B, 2C, 3AB, 3B^{VPg}, 3CD^{pro}, 3D^{pro}). The genome of FMDV encodes three VPg proteins. The genome of Ljungan virus, a parechovirus, may encode two unrelated 2A proteins²⁴⁹ and that of duck hepatitis A virus in the genus *Avihepatovirus* encodes three 2A motifs.

INFECTIOUS DNA CLONES OF PICORNAVIRUS GENOMES

Recombinant DNA techniques allow the introduction of mutations anywhere in the genome of most animal viruses. An infectious DNA clone—a double-stranded copy of the viral genome carried on a bacterial plasmid—or RNA transcripts derived by *in vitro* transcription, can be introduced into cultured cells by transfection to recover infectious virus. The first infectious DNA clone of an animal RNA virus was that of poliovirus.⁴¹⁶ The infectivity of cloned poliovirus DNA (10³ pfu/μg) is much lower than that of genomic RNA (10⁶ pfu/μg). The development of plasmid vectors incorporating promoters for bacteriophage SP6, T7, or T3 RNA polymerase for the production of RNA transcripts *in vitro* enabled the production of infectious picornavirus RNA from cloned DNA.⁵⁰³ Such RNA transcripts have an infectivity approaching that of genomic RNA. A similar approach has been adopted for the recovery of many other picornaviruses from cloned DNA copies of the viral genome.

STAGES OF REPLICATION

Replication of picornaviruses occurs in the cell cytoplasm. The first step is attachment to a cell receptor (Fig. 16.4). The RNA genome is then uncoated, a process that involves structural changes in the capsid. Once the positive-stranded viral RNA enters the cytoplasm, it is translated to provide viral proteins essential for genome replication and the production of new virus particles. The viral proteins are synthesized from a polyprotein precursor, which is cleaved nascently. Cleavages are carried out mainly by two viral proteinases, 2A^{pro} and 3C^{pro} or 3CD^{pro}. Among the proteins synthesized are the viral

FIGURE 16.4. Overview of the picornavirus replication cycle. Virus binds to a cellular receptor (1) and the genome is uncoated (2). VPg (viral protein, genome linked) is removed from the viral RNA, which is then translated (3). The polyprotein is cleaved nascently to produce individual viral proteins (4). RNA synthesis occurs on membrane vesicles induced by viral proteins (not drawn to scale). Viral (–) strand RNA is copied by the viral RNA polymerase to form full-length (–) strand RNAs (5), which are then copied to produce additional (+) strand RNA (6). Early in infection, newly synthesized (+) strand RNA is translated to produce additional viral proteins (7). Later in infection, the (+) strands enter the morphogenetic pathway (8). Newly synthesized virus particles are released from the cell by lysis (9).

RNA-dependent RNA polymerase and accessory proteins required for genome replication and mRNA synthesis. The first step in genome replication is copying of the positive-stranded RNA to form a negative-stranded intermediate; this step is followed by the production of additional positive strands. These events occur on small membranous vesicles that are induced by several virus proteins. Once the pool of capsid proteins is sufficiently large, encapsidation begins. Coat protein precursor P1 is cleaved to produce an immature protomer, which then assembles into pentamers. Newly synthesized, positive-stranded RNA associates with pentamers to form the infectious virus. Empty capsids that are found in infected cells are likely to be a storage form of pentamers.

The entire time required for a single replication cycle ranges from 5 to 10 hours, depending on many variables, including the particular virus, temperature, pH, host cell, and

multiplicity of infection. Many picornaviruses are released as the cell loses its integrity and lyses. Other picornaviruses (e.g., hepatitis A virus) are released from cells in the absence of cytopathic effect.

ATTACHMENT

Cellular Receptors and Coreceptors

Like most viruses, picornaviruses initiate infection of cells by first attaching to a receptor on the host cell plasma membrane. The nature of picornavirus receptors remained obscure until 1989, when the receptors for poliovirus and the major group rhinoviruses were identified.^{184,332,471} Receptors for many other members of this virus family have since been identified (Table 16.3). Different types of cell surface molecules serve as

TABLE 16.3 Some Cell Receptors for *Picornaviruses*

Virus	Virus receptor	Type of receptor	Coreceptor	References
Aphthovirus				
Foot-and-mouth disease virus (cell culture adapted)	Heparan sulfate	Glycosaminoglycan		(236)
Foot-and-mouth disease virus	$\alpha_v\beta_1$, $\alpha_v\beta_3$, $\alpha_v\beta_6$, $\alpha_v\beta_8$	Integrin		(237,238,351)
Equine rhinitis A virus	Sialic acid	Carbohydrate		(473)
Cardiovirus				
Encephalomyocarditis virus	Vcam-1	Ig-like		(227)
	Sialylated glycoporphin A (for hemagglutination only)	Carbohydrate		
Theiler's murine encephalomyelitis virus	Sialic acid	Carbohydrate		(193)
Low neurovirulence strains	Sialic acid	Carbohydrate		(302)
High neurovirulence strains	Heparin sulfate	Proteoglycan		
Enterovirus				
Bovine enterovirus	Sialic acid	Carbohydrate		(547)
Coxsackievirus A9	$\alpha_v\beta_3$, $\alpha_v\beta_6$	Integrin	β_2 -Microglobulin, GRP78, MHC-1	(431,498,499, 531)
Coxsackieviruses A13, A18, A21	Icam-1 (CD)	Ig-like		(99)
Coxsackievirus A16	P-selectin glycoprotein ligand-1 (PSGL-1), Scavenger receptor class B (SCARB2)	Mucin-like		(360,539)
Coxsackievirus A21	Decay-accelerating factor (CD55)	SCR-like (complement cascade)	Icam-1	(453)
Coxsackievirus A24	Sialic-acid containing, O-linked glycoconjugates	Carbohydrate		(336,359)
Coxsackieviruses B1–B6	Car (coxsackievirus-adenovirus receptor)	Ig-like		(58)
Coxsackievirus B1, B3, B5	Decay-accelerating factor (CD55)	scr-like (complement cascade)	$\alpha_v\beta_6$ -Integrin (CVB1) CAR (CVB3)	(4,452,454)
Echovirus 1, 8	$\alpha_2\beta_1$ -Integrin (Vla-2)	Integrin	β_2 -Microglobulin	(56,521)
Echovirus 3, 6, 7, 11–13, 20, 21, 24, 29, 30, 33	Decay-accelerating factor (CD55)	SCR-like (complement cascade)	β_2 -Microglobulin, CD59 (E7)	(57,172,409, 437,520,521)
Echovirus 5	Heparan sulfate	Proteoglycan		(234)
Echovirus 9	$\alpha_v\beta_3$ -Integrin	Integrin		(352)
Enterovirus 70	Decay-accelerating factor (CD55) sialic acid	SCR-like (complement cascade) carbohydrate		(8,264)
Enterovirus 71	P-selectin glycoprotein ligand-1 (PSGL-1), Scavenger receptor class B (SCARB2)	Mucin-like		(360,539)
Parechovirus 1	$\alpha_v\beta_3$, $\alpha_v\beta_6$			(497)
Parechovirus 1	$\alpha_v\beta_1$, $\alpha_v\beta_3$ (Vitronectin receptor)	Integrin		(497)
Hepatitis A virus	HAVcr-1	T-cell Ig-like, mucin-like (TIM)		(261)
Polioviruses 1–3	Pvr (CD155)	Ig-like		(332)
Rhinoviruses (major group, 91 serotypes)	Icam-1	Ig-like		(184,471,492)
Rhinoviruses (minor group, 10 serotypes)	Low-density lipoprotein receptor protein family	Signaling receptor		(222)

Ig, Immunoglobulin; SCR, short consensus repeat.

cellular receptors for picornaviruses; some are shared among picornaviruses and members of other virus families. For example, the cell surface protein CD55 is a receptor for certain Coxsackieviruses, echoviruses, and enterovirus 70, and the PVR CD155 is a receptor for alphaherpesviruses. For some picornaviruses (e.g., poliovirus and rhinovirus), a single type of receptor is sufficient for entry of viruses into cells. For other viruses, a second molecule, or coreceptor, is needed for virus entry into cells. For example, Coxsackievirus A21, which attaches to CD55, requires intercellular adhesion molecule 1 (ICAM-1) for entry into cells.⁴⁵³

One Type of Receptor Molecule for Virus Binding and Entry

For certain picornaviruses, a single type of receptor molecule is sufficient for virus binding and entry. These include the cell receptors for poliovirus (PVR/CD155), rhinoviruses (ICAM-1, low-density lipoprotein receptor LDLR, LDLR-related protein, very-low-density lipoprotein receptor), EMCV (VCAM-1), hepatitis A virus (TIM-1), and enterovirus 71 (SCBR2, PSGL-1).

The PVR is a type I transmembrane protein and a member of the immunoglobulin (Ig) superfamily of proteins, with three extracellular Ig-like domains: a membrane-distal V-type domain followed by two C2-type domains.³³² Production of PVR in mice is sufficient to overcome the lack of susceptibility of this species to poliovirus infection.^{282,421} Because PVR transgenic mice develop poliomyelitis after inoculation with poliovirus by different routes, they have proved to be a valuable model for studying the pathogenesis of poliomyelitis.⁴¹⁷ PVR transgenic mice are not susceptible to infection by the oral route, the natural route of infection in humans, unless the gene encoding type I interferon receptors has been deleted.^{370,549} PVR is synthesized in many tissues in transgenic mice, yet the main sites of poliovirus replication are the brain and spinal cord.^{282,422} This restricted tropism is regulated by the interferon (IFN)- α/β response, which limits viral replication in extraneural organs.²³²

Expression of PVR on cultured cells derived from different animal species leads to susceptibility to poliovirus infection. Therefore it is likely that PVR is the only molecule required for poliovirus binding and entry. The observation that a monoclonal antibody directed against the lymphocyte homing receptor CD44 blocks poliovirus binding to cells suggests that this protein might be a coreceptor for poliovirus entry.^{456,457} It was subsequently shown that CD44 is not a receptor for poliovirus and is not required for poliovirus infection of cells that produce PVR.^{72,149} It seems likely that PVR and CD44 are associated in the cell membrane¹⁵⁰ and that anti-CD44 antibodies block poliovirus attachment by blocking the poliovirus-binding sites on PVR.

Orthologs of the *pvr* gene are present in the genomes of a number of mammals, including those not susceptible to poliovirus infection.²³¹ The amino acid sequence of domain 1 of PVR varies extensively among the nonsusceptible mammals, especially in the regions known to contact poliovirus. The absence of a poliovirus-binding site on these PVR molecules, therefore, explains why poliovirus infection is restricted to simians.

The PVR is an adhesion molecule that participates in the formation of adherens junctions through interaction with nectin-3, a related immunoglobulin-like protein.³⁴⁹ The PVR is

also a recognition molecule for natural killer (NK) cells, and interacts with CD226 and CD96 on NK cells to stimulate their cytotoxic activity.^{71,153} It also interacts with T-cell Ig and ITIM domain (TIGIT), regulating T-cell function.³⁰⁸ The UL141 protein of cytomegalovirus (CMV) blocks surface expression of PVR, leading to evasion of NK cell-mediated killing.⁴⁹¹

The cell surface receptor for the major group of human rhinoviruses (90 serotypes) was identified by using monoclonal antibodies directed against the cellular binding site to isolate the receptor protein from susceptible cells. Amino acid sequence analysis of the purified protein revealed that it is ICAM-1, a type I transmembrane protein with five immunoglobulin-like domains.^{184,471,492} The normal cellular functions of ICAM-1 are to bind its ligand, lymphocyte function-associated antigen 1 (LFA-1) on the surface of lymphocytes and to promote a wide range of immunologic functions.⁵⁰² ICAM-1 is expressed on the surfaces of many tissues, including the nasal epithelium, which is the entry site for rhinoviruses.

Three members of the low-density lipoprotein receptor family are receptors for minor group rhinoviruses (10 serotypes). These proteins consist of 7 (LDLR), 8 (VLDLR), or 31 (LRP) ligand-binding repeats, transmembrane and cytoplasmic domains.

Many picornaviruses bind integrins, which are dimeric cell adhesion receptors with α and β subunits. Many integrin receptors recognize the tripeptide Arg-Gly-Asp (RGD) whose presence in the viral capsid suggests interaction with this type of receptor. A number of integrins can serve as entry receptors for FMDV (Table 16.3), although all may not be utilized during infection of animals. Although integrins are sufficient for FMDV infection, their interaction with the viral capsid does not lead to uncoating (see *Entry Into Cells*).

Receptors and Coreceptors Required for Infection

Many enteroviruses bind to decay-accelerating factor (DAF, or CD55), a member of the complement cascade (Table 16.3); it is composed of four extracellular short consensus repeat modules and is attached to the plasma membrane by a glycosylphosphatidyl inositol (GPI) anchor. For most of these viruses, however, interaction with DAF is not sufficient for infection; this molecule is an attachment receptor but does not lead to virion uncoating. For example, Coxsackievirus A21 binds to DAF, but infection does not occur unless ICAM-1 is also bound (Fig. 16.5).⁴⁵³ In this case, ICAM-1 inserts into the canyon where it triggers capsid uncoating.⁵³⁴ Coxsackievirus B3 binds DAF but virion uncoating does not occur unless Coxsackievirus-adenovirus receptor (CAR; see below) binds in the canyon.²⁰⁸

Echovirus 7, which normally binds DAF, can infect some DAF-negative cells; in these cases CD59 or β_2 -microglobulin can serve as coreceptors for entry.^{172,521} Some Coxsackie B viruses that bind CD55 may require $\alpha_5\beta_1$ -integrin as a coreceptor.⁴

A specific role for coreceptors in virus entry is illustrated by Coxsackievirus B3 entry into polarized epithelial cells.¹⁰⁵ The Coxsackievirus and adenovirus receptor, CAR, mediates cell entry of all Coxsackie B viruses.⁵⁸ CAR is not present on the apical surface of epithelial cells that line the intestinal and respiratory tracts, but is a component of the tight junction and is inaccessible to virus entry. Coxsackie B viruses first bind an attachment receptor, DAF, which is present on the apical

FIGURE 16.5. Interactions of six different picornaviruses with cellular receptors. Immunoglobulin-like cell receptors bind in the canyon, as illustrated for coxsackievirus 21 and ICAM-1, coxsackievirus B3 and CAR, rhinovirus 16 and ICAM-1, and poliovirus type 1 with PVR. A receptor for rhinovirus type 2, very-low-density lipoprotein receptor, binds on the plateau at the fivefold axis, and DAF binds echovirus 7 near the twofold icosahedral axes. Images produced with the Virus Particle Explorer at viberdb.scripps.edu.⁸³

surface of epithelial cells. Coxsackievirus B3 binding to DAF activates Abl kinase, which in turn triggers Rac-dependent actin rearrangements, leading to virus movement to the tight junction where it can bind CAR and enter cells.¹⁰⁵

Enteroviruses that bind integrins typically require a coreceptor for cell entry. For CAV9, it has been suggested that β_2 -microglobulin,⁴⁹⁹ GRP78, and MHC-1⁴⁹⁸ might fulfill this role.

Alternative Receptors

Some viruses bind to different cell surface receptors, depending on the virus isolate or the cell line (Table 16.3). Clinical isolates of FMDV bind to integrin receptors, but passage in cell culture can select for viruses that bind to heparin sulfate, a sulfated glycan.^{236,320,443} Cell culture passage may also produce a virus that infects cells independent of heparin sulfate and integrins.³³

How Picornaviruses Attach to Cell Receptors

Among the picornavirus members, the four capsid proteins are arranged similarly, but the surface architecture varies. These dif-

ferences account for both the diverse serotypes and the varied modes of interaction with cell receptors. For example, the capsids of enteroviruses have a groove, or canyon, surrounding each fivefold axis of symmetry. In contrast, coronaviruses and aphthoviruses do not have canyons.

The canyons of enteroviruses are the sites of interaction with Ig-like cell receptors. The results of genetic and structural experiments demonstrate that the first Ig-like domain contains the site that binds poliovirus. Cells expressing the first Ig-like domain of PVR, either alone or as a hybrid with other Ig-like proteins, are susceptible to infection with poliovirus.^{281,342,450,451} Mutations in the first Ig-like domain of PVR interfere with poliovirus binding.^{21,60,343} Mutagenesis of ICAM-1 DNA has revealed that the binding site for rhinovirus is located in the first Ig-like domain.^{325,420,472} Models of the interaction of poliovirus, rhinovirus, and Coxsackievirus with their cellular receptors have been produced from cryo-EM and x-ray crystallographic data (Fig. 16.5).^{51,53,84,85,207,283,372,536} These models reveal that only domain 1 of PVR or ICAM-1 penetrates the

canyon of the respective virus. Mutations that affect receptor binding map to the virion–receptor interface as determined by these structural studies. Mutation of amino acids that line the canyons of poliovirus and rhinovirus can alter the affinity of binding to receptors.^{100–102,204,300}

Although the capsids of at least two minor group rhinoviruses possess a canyon around the fivefold axes, it is not the binding site for the minor group receptor, members of the low-density lipoprotein receptor family (Fig. 16.5). Rather, the minor group receptor binds close to the fivefold axis, on the star-shaped plateau that is surrounded by the canyon.^{213,413,418,512} In this way multiple low-affinity interactions are combined to yield a high-avidity virus–receptor complex.

Sequence and structural comparisons have revealed why major and minor group rhinoviruses recognize different receptors. A lysine at position 224 of VP1, which is conserved in all minor group rhinoviruses, is the key amino acid that interacts with a negatively charged cluster of LDLR.⁵¹² The electrostatic attraction between Lys1224 and the acidic cluster in LDLR might initiate contact between virus and receptor. Neighboring hydrophobic and basic residues in VP1 could then lead to tight binding between virus and receptor. The conserved lysine is not present in VP1 of major group rhinoviruses, providing an explanation for failure of these viruses to bind LDLR. An exception is rhinovirus 85, a major group serotype that has the conserved lysine; presumably, it does not bind LDLR because of other amino acid differences in neighboring hydrophobic and basic VP1 residues.

It was originally believed that the picornavirus canyons were too deep and narrow to allow penetration by antibody molecules, which contain adjacent immunoglobulin domains.⁴³⁶ This physical barrier was believed to hide amino acids crucial for receptor binding from the immune system. Structural studies of a rhinovirus–antibody complex, however, revealed that antibody does penetrate deep into the canyon, as does ICAM-1.⁴⁶³ The shape of the picornavirus canyon, therefore, is not likely to play a role in concealing virus from the immune system.

In contrast to the Ig-like receptors that bind the canyons of enteroviruses, the binding sites for DAF on the virion are diverse. For example, DAF bridges the canyon of Coxsackievirus B3.¹⁹⁶ In contrast, the binding site of DAF on echovirus 7 (Fig. 16.5) and 12 is near the twofold axis.^{390,402} These interactions are not sufficient for virion uncoating. Coxsackievirus A21 must also bind ICAM-1, which inserts into the canyon, triggering capsid uncoating.^{453,534} Similarly, Coxsackievirus B3 binds DAF but virion uncoating does not occur unless CAR binds in the canyon.²⁰⁸

Integrin-binding picornaviruses attach to cell receptors through surface loops. In FMDV, an Arg-Gly-Asp sequence in the flexible, exposed β G- β H loop of the capsid protein VP1 is recognized by integrin receptors on cells.^{121,147,306} Arg-Gly-Asp-containing peptides block attachment of FMDV,⁴⁴ and alteration of this sequence interferes with virus binding.³²² In Coxsackievirus A9, the Arg-Gly-Asp sequence is present in a 17–amino acid extension of the C-terminus of VP1 and is also the site of attachment to cell receptors.^{87,431} Alteration of this sequence does not abolish binding to cells, suggesting that the virus can bind to another cell surface receptor.²²⁸ Echovirus 1 is unusual in that it binds the RGD-independent integrin $\alpha_2\beta_1$ in the canyon.⁵³⁷

As discussed, FMDV binds alternative receptors, either integrin or heparan sulfate, depending on the virus isolate. The binding site for heparan sulfate on cell culture–adapted FMDV

is a shallow depression on the virion surface, where the three major capsid proteins, VP1, VP2, and VP3, are located.¹⁵² Binding specificity is controlled by two preformed sulfate-binding sites on the capsid. Residue 56 of VP3 is a critical regulator of receptor recognition. In field isolates of the virus, this amino acid is histidine. Adaptation to cell culture selects for viruses with an arginine at this position, which forms the high-affinity, heparan sulfate-binding site.

The interaction of EMCV with its cellular receptor, VCAM-1, has not been studied in detail. The EMCV capsid does not have a canyon, therefore VCAM-1, an Ig-like protein, must interact with the virion in a manner different from the Ig-like receptors of poliovirus and rhinovirus.

Kinetics and Affinity of the Virus–Receptor Interaction

The affinity and kinetics of picornaviruses binding to soluble forms of their receptors have been studied by surface plasmon resonance. Two classes of receptor-binding sites, with distinct binding affinities, exist on the capsids of poliovirus and rhinovirus.^{84,326,536} The association rates for the two binding classes are 25 and 13 times higher for the poliovirus–sPVR interaction than for the rhinovirus–sICAM interaction at 20°C. The greater association rate of poliovirus and PVR may be caused, in part, by differences in the extent of contact between virus and receptor. In contrast, whereas two dissociation rate constants exist for the poliovirus–PVR interaction, only one has been reported for the rhinovirus 3–ICAM interaction. The dissociation rates for the poliovirus–sPVR interaction are 1.5 times and 2.0 times faster than for the rhinovirus–sICAM interaction, indicating greater instability of the former complex. The affinity constants for the poliovirus–sPVR interaction are 19 times and 6 times greater than those reported for the rhinovirus–sICAM-1 complex.

In contrast to the observations with poliovirus and rhinovirus, a single class of binding site was found on echovirus 11 for a soluble form of its receptor, CD55.²⁹² The affinity of this interaction is at least fourfold lower than either of the binding sites on poliovirus for sPVR. The association rate for the interaction between echovirus 11 and CD55 is faster than that of poliovirus–sPVR and rhinovirus–sICAM-1. One explanation for these findings is that the contact between echovirus 11 and CD55 is more extensive than that of the other two virus–receptor complexes. The binding site for CD55 on echovirus 11 may also be more accessible than those of PVR and ICAM-1. The dissociation rate for the echovirus–CD55 interaction is at least 97 times faster than that of either the poliovirus–sPVR or the rhinovirus–sICAM-1 interaction. These findings are consistent with a more accessible binding site for CD55 on echovirus 11, compared with the receptor-binding sites on poliovirus and rhinovirus. Atomic interactions between CD55 and echovirus 11 may be weaker than between the other two viruses and their receptors. The faster dissociation rate of the echovirus 11–CD55 complex may be related to the finding that the interaction does not lead to structural changes of the virus particle,⁴⁰⁹ as occurs with poliovirus and rhinovirus. In general, there is a higher affinity for virions of receptors that can uncoat particles (“unzippers”—poliovirus/PVR, HRV/ICAM-1, CVB3/CAR) compared with attachment receptors (E6, 7, 11, 12, CVB3 with DAF). This may reflect the requirement for higher affinity to release the viral RNA.

Why do poliovirus and rhinovirus have two classes of receptor-binding sites? The receptors for both viruses make contacts at two major sites on the virus surface, one in a cleft on the south rim of the canyon, and a second on the side of the mesa on the north rim. These two contact sites may correspond to the two classes of binding sites. Two classes of binding sites may also be a consequence of the structural flexibility exhibited by both viruses, which may cause exposure of different binding sites. Normally internal parts of the poliovirus and rhinovirus capsid proteins have been shown to be transiently displayed on the virion surface, a process called *breathing*.^{296,298} As to be discussed later, the interaction of poliovirus and rhinovirus with their cellular receptors leads to irreversible and more extensive structural changes. In contrast to the findings with poliovirus and rhinovirus, binding of echovirus 11 with CD55 can be described by a simple 1:1 binding model. Such behavior, which would be expected for the interaction of two preformed binding sites, is consistent with the fact that the echovirus–CD55 interaction does not result in detectable structural changes in the capsid.⁴⁰⁹

ENTRY INTO CELLS

Once picornaviruses have attached to their cellular receptor, the viral capsid is brought into the cell by the endocytic pathway, followed by genome release into the cytoplasm, the site of picornavirus replication. For some picornaviruses, interaction with a cell receptor serves only to concentrate virus on the cell surface; release of the genome is a consequence of low pH or perhaps the activity of a coreceptor. For other picornaviruses, the cell receptor is also an unzipper and initiates conformational changes in the virus that lead to release of the genome.

Entry by Clathrin-Mediated Endocytosis

Several lines of evidence indicate that FMDVs enter cells by clathrin-mediated endocytosis. Infection is inhibited by sucrose, which eliminates clathrin-coated pits and induces clathrin to polymerize into empty cages, and by expression of a dominant negative form of the clathrin coat assembly protein AP180 that is needed for assembly of clathrin cages.⁶¹ Confocal microscopy also revealed that FMDV enters cells via a clathrin-dependent mechanism.³⁶⁶ There is also some evidence that entry is dependent on cholesterol in the plasma membrane, a requirement generally observed for lipid rafts³¹⁹; however, cholesterol might be required for clathrin-induced membrane curving.⁴²⁸ Another aphthovirus, equine rhinitis A virus, binds sialic acid-containing receptors but also enters into cells via clathrin-mediated endocytosis.¹⁸⁵

LDLR family members that are receptors for minor group HRVs possess C-terminal cytoplasmic domains with tyrosine- and di-leucine-based internalization signals that lead to clustering of the receptors in clathrin-coated pits.³⁸⁴ Evidence for HRV entry via this pathway includes the inhibition of infection in cells producing dominant negative inhibitors of the clathrin pathway.^{47,465} There is some evidence that ICAM-1 binding major group HRVs also enter cells via clathrin-mediated endocytosis, including transmission EM, which shows virions in clathrin-coated pits and vesicles 5 minutes after infection¹⁸⁷ and the fact that dominant negative dynamin inhibits infection.¹¹⁸ HRV infection also activates signaling pathways with

links to the endocytic machinery. The cytoplasmic domain of ICAM-1 binds the adaptor protein ezrin, which links the receptor to Syk, a tyrosine kinase.^{519a} When HRV binds ICAM-1, Syk is recruited from the cytoplasm to the plasma membrane together with clathrin. Functional Syk is required for HRV entry via ICAM-1.²⁹¹

When virions enter cells by clathrin-dependent endocytosis they encounter low pH, which triggers release of the viral RNA from the capsid. A role for low pH in infection can be demonstrated by determining the effect on entry of compounds that block acidification, such as weak bases (ammonium chloride, chloroquine, methylamine) ionophores (monensin, nigericin, X537A) or inhibitors of the vacuolar proton ATPase (concanamycin A, bafilomycin A). The pH of early endosomes is 6.5; as these vesicles mature to late endosomes the pH drops to 5.5. Endosomal maturation is dependent not only on vacuolar ATPases but also on microtubules and membrane GTPases of the Rab family. Early to late endosome maturation can be inhibited by drugs that depolymerize microtubules (nocodazole), dominant negative Rabs, or inhibitors of PI3K signaling (wortmannin). In this way it is possible to determine if viral entry occurs from early or late endosomes.

Uncoating by FMDV clearly requires low pH because concanamycin A, monensin, and ammonium chloride all inhibit infection.^{43,61,366,517} Entry occurs from the early endosome as determined by experiments with dominant negative Rab proteins.²⁵⁰ FMDV that bind heparan sulfate enter cells via a caveolae-dependent route, but low pH is still required for infection.³⁶⁷ Consistent with this mechanism of uncoating, FMDV that has been coated with antibody can bind to, and infect, cells that express Fc receptors, in contrast to poliovirus, which cannot productively infect cells via this pathway.³²¹ Cell receptors for FMDV are, therefore, *hooks*: they do not induce uncoating-related changes in the virus particle, but rather serve only to tether the virus to the cell and bring it into the endocytic pathway.

Entry of minor group HRVs requires low pH of the late endosome, as infection is inhibited by monensin, bafilomycin A1, nocodazole, and wortmannin.^{46,59,74,353,410} ICAM-binding HRVs are also sensitive to bafilomycin and monensin, suggesting that endosome acidification is required for entry.^{187,387,483}

Echovirus 7, which binds DAF, enters cells by clathrin-mediated endocytosis, and trafficking into late endosomes is required.²⁷⁰ However, infection does not appear to require low pH, and therefore the trigger for uncoating and its intracellular location remains in question.

Entry by Caveolin-Mediated Endocytosis

As discussed above, CVB3 binds DAF, a GPI-linked protein localized within lipid rafts on the apical surface of polarized cells. The virus/DAF complex then moves to tight junctions (TJ) where it engages CAR. The virus is then internalized along with the TJ protein occludin by caveolin-1-dependent endocytosis.¹⁰⁷ The role of occludin is not known but it could provide a scaffold for recruiting other molecules. Within 60 minutes, the virus is within caveolin-1-containing vesicles (caveolae and caveosomes). Phosphorylation of caveolin-1 by tyrosine kinases is required for CVB3 entry, but the role of this modification is not known. Dynamin is not required for uptake of this virus, suggesting that other routes of entry are involved. Inhibitors of micropinocytosis (rotterin and dominant negative Rab34) block infection, indicating a role for this type of uptake.

Echovirus 1, which binds the integrin $\alpha 2 \beta 1$, is taken into the cell by the caveolin-mediated endocytic pathway. The receptor is present in raft-like membrane domains that do not contain caveolin. Internalization of the virus does not depend on dynamin, but components of the macropinocytosis pathway, such as PKC, Pak1, and Rac1, are involved. By 30 minutes after infection, the virus appears in vesicular structures that appear to be caveolae.³¹⁸ These fuse with caveosomes, delivering the virus and its receptor to the perinuclear region.³⁹⁷ These may be novel multivesicular bodies; virus transport to them appears to depend on ESCRT proteins.²⁶³

Caveolin- and Clathrin-Independent Endocytosis

In HeLa cells, poliovirus is taken up into cells by an endocytic pathway that is dependent on actin, ATP, and a tyrosine kinase, but independent of clathrin, caveolin, flotillin, microtubules, and pinocytosis.⁷⁶ RNA release from the particle occurs rapidly and within 100 to 200 nm of the cell surface. Entry was different in a highly polarized human brain microvascular endothelial cell line.¹⁰⁶ Poliovirus enters these cells very slowly via dynamin-dependent caveolar endocytosis. Virus binding to PVR induces tyrosine phosphorylation of the receptor cytoplasmic domain, which in turn recruits and activates SHP-2, which is required for infection. These observations emphasize that virus entry pathways are likely to differ substantially according to cell type.

Uncoating

The interaction of enteroviruses and major group rhinoviruses with susceptible cells leads to the conversion of virions to a

more slowly sedimenting form (135S versus 160S for native particles).^{112,252} The resulting particles, called *altered* (or *A*) *particles*, contain the viral RNA but have lost the internal capsid protein VP4. In addition, the N-terminus of VP1, which is normally on the interior of the capsid, is on the surface of the A particle.¹⁵¹ This sequence of VP1 is hydrophobic and, as a result, the A particles have an increased affinity for membranes compared with the native virus particle. It is believed that A particles represent a stable intermediate structure in the entry process that terminates with exit of RNA and the production of empty (80S) capsids. In one hypothesis for poliovirus entry, receptor binding leads to these conformational changes; the exposed lipophilic N-terminus of VP1 then inserts into the cell membrane, tethering the A particle to the membrane. A membrane pore is then formed, possibly by both VP4 and VP1, through which the viral RNA can travel to the cytoplasm (Fig. 16.6). The finding that A particles, when added to lipid bilayers, induce the formation of ion channels supports this hypothesis.⁴⁹³ The trigger for conversion of minor group HRVs is not receptor binding but low pH.⁴¹⁰

Native poliovirus and rhinovirus particles have been shown to transiently and reversibly expose VP4 and the N-terminus of VP1, a process called “breathing”.^{296,298} Receptor binding (poliovirus) or low pH (rhinoviruses, cardioviruses, aphthoviruses) lowers the energy barrier for conversion to the A particle, a process that enables genome delivery to the cell. The structure of poliovirus bound to a monoclonal antibody that recognizes the N-terminus of VP1 reveals that this viral protein exits the capsid near the twofold axes, instead of near the propeller tip in 135S particles (see below).

FIGURE 16.6. Hypothetical mechanism for translocation of poliovirus RNA across the cell membrane. A: Cross-section of a virus particle that has just bound poliovirus receptor (PVR) at the cell surface. PVR docks on the capsid in the canyon, above the hydrophobic pocket. The path of VP1 egress would not preclude continued binding to PVR. The viral RNA is in the capsid, and lipid has exited from the hydrophobic pocket. The capsid is colored blue, VP4 is green, and the N-terminus of VP1 is cyan and magenta, PVR is tan, RNA is a green line. At this stage the VP3 β -cylinder (red) blocks a channel at the fivefold axis. **B–D** illustrate alternative models for anchoring of virus particle to the cell membrane by the N-terminus of VP1 and formation of a pore for passage of viral RNA. Upon binding, PVR structural changes occur that move the VP3 β -cylinder out of the way like a float valve and open a channel at the fivefold axis that is contiguous with a pore in the membrane. **(B)** Amphipathic helices at the N-terminus of VP1 form a pore through the membrane. In **C** and **D**, VP4 (green mesh) is playing a central role in pore formation. In this case, VP1 may anchor the particle to the membrane. An alternative pathway for release of the genome from the base of the canyon is shown.

Low-resolution, cryo-EM reconstructions of the poliovirus 135S and 80S particles did not reveal openings that could allow for release of the viral genome.⁵² Subsequently, higher-resolution structures of the poliovirus A particle and a derivative in which the N-terminal 31 amino acids of VP1 were removed revealed that this sequence of VP1 is likely to exit the virion at the base of the canyon, between the tips of the “stars” at the fivefold axis and the propeller-shaped feature around the threefold axis.⁷⁸ It has also been suggested that VP4 exits near the twofold axis, based on the observation that insertion of a cysteine in the N-terminus of VP4 leads to disulfide linking upon breathing.²⁶⁶

Cryo-EM reconstructions of 80S particles of HRV2,²¹³ HRV14, and poliovirus²⁹⁵ reveal two populations of particles, one with more internal density (presumably RNA) than the other. The poliovirus structures reveal different particle states: some in the process of releasing RNA, others with nucleic acid in the particle, crossing the particle walls, and outside the particle. Analysis of these particles indicates that the viral RNA exits the capsid from openings at the base of the canyon, near where the release of the VP1 N-terminus occurs.⁷⁰ The trigger for release of RNA from the capsid is unknown, but may require unfolding of secondary structure.⁷⁶

VP4 is released from the virion during conversion to A particles, but a small amount of this protein might remain and participate with VP1 in membrane channel formation. A virus containing an amino acid change at position 28 of VP4 can bind to cells and be converted to A particles, but these are blocked at a subsequent step in virus entry.³⁴⁵ Amino acid changes at this position of VP4 reduce the conductance of ion channels and the translocation of viral RNA.¹¹⁵ These findings suggest that VP4 might play a central role in pore formation. VP4 and VP2 are produced, during virus assembly, from the precursor VP0, which remains uncleaved until RNA encapsidation. Cleavage of VP0, therefore, can be viewed as a way of priming the capsid for uncoating because cleavage separates VP4 from VP2.

While the enterovirus capsid maintains its icosahedral form during uncoating, the acid-labile aphthoviruses dissociate into pentamers at low pH, a process that releases the viral RNA.⁵¹⁰ The mechanism by which low pH causes disassembly of the FMDV capsid has been illuminated by structural and genetic studies. Examination of the atomic structure of the virus revealed a high density of histidine residues lining the pentamer interfaces, which are stabilized by β -sheet interactions.¹ These residues confer stability to the capsid; because the pKa of histidine is 6.8, close to the pH at which the virus dissociates, protonation of the side chains of the histidines might cause electrostatic repulsion, leading to disassembly.¹¹³ To test this hypothesis, a histidine residue at position 142 of VP3 was changed to arginine by mutagenesis. The resulting capsids were more stable at low pH than wild-type capsids,¹³⁴ supporting the proposed role of the histidine residue in acid-catalyzed disassembly. Enteroviruses are stable at low pH in part because there are extra β -sheet interactions in VP1.¹³⁸ Equine rhinitis A virus is also acid labile; it dissociates into pentamers due to rearrangement of loops in VP2 that disrupt the pentamer interfaces.⁵⁰¹ How aphthoviruses breach the endosome membrane is not known; these viruses do not have a hydrophobic VP1 N-terminus, and A particles are not produced.

If aphthoviruses dissociate into pentamers in the endosome, how is the integrity of viral RNA preserved before it exits to the cytoplasm? A clue is provided by the finding that equine rhinitis A virus capsid dissociation is preceded by the formation of a transient empty particle.⁵⁰¹ It is possible that this protects the viral RNA until it leaves the endosome.

Low pH causes particle expansion of minor group rhinoviruses and the opening of a 10 Å diameter pore at the fivefold axis through which the RNA is presumed to exit.²¹⁴

Regulation of Uncoating by Cellular Molecules

Beneath the canyon floor is a hydrophobic pocket that opens at the base of the canyon and extends toward the fivefold axis of symmetry. The pocket appears to be occupied in many picornaviruses with a fatty acid or related compound (Fig. 16.2). In some picornaviruses (e.g., rhinovirus types 3 and 14), the pockets are apparently empty.^{25,550} The hydrophobic pocket appears to be a critical regulator of the receptor-induced structural transitions of enteroviruses. The icosahedral symmetry of the capsid would allow each virion to contain up to 60 lipid molecules. Certain antiviral drugs (e.g., the WIN compounds first identified by Sterling-Winthrop, Inc.) displace the lipid and bind tightly within the pocket.⁴⁶² Binding of such drugs to rhinovirus 14 causes conformational changes in the canyon that prevent attachment to cells.³⁹¹ In contrast, drug binding to rhinoviruses 1A, 3, and 16 and to poliovirus causes smaller structural changes in the capsid.^{182,195,218} Inhibition of rhinovirus 16 binding by these compounds is probably not a consequence of altering the receptor-binding site, but rather the result of preventing conformational changes required for receptor binding. Such compounds do not inhibit binding of poliovirus, but rather uncoating.³³⁰

The lipids that occupy the hydrophobic pocket were originally believed to contribute to the stability of the native virus particle by locking the capsid in a stable configuration and preventing conformational changes. Removal of the lipid was therefore necessary to provide the capsid with sufficient flexibility to undergo the changes that permit the RNA to leave the shell. This hypothesis comes from the study of antiviral drugs, such as the WIN compounds, that displace the lipid and bind tightly in the hydrophobic pocket. These antiviral compounds block breathing of the rhinovirus capsid, the process by which normally internal parts of the capsid proteins are transiently displayed on the virion surface.²⁹⁶ Polioviruses containing bound WIN compounds can bind to cells, but the interaction with PVR does not result in the production of A particles.^{148,548} WIN compounds appear to inhibit poliovirus infectivity by preventing PVR-mediated conformational alterations that are required for uncoating. Additional support for the role of lipids in uncoating comes from the analysis of poliovirus mutants that cannot replicate unless WIN compounds are present.³⁴⁷ Such WIN-dependent mutants spontaneously convert to altered particles at 37°C, in the absence of the cell receptor, probably because of the absence of lipid in the hydrophobic pocket. The lipids can be considered to be switches that determine whether the virus is stable (lipid present) or will uncoat (lipid absent). It is not known what causes lipid release from the capsid. PVR docks onto the poliovirus capsid just above the hydrophobic pocket (Fig. 16.6), which suggests that the interaction of the virus with receptor may initiate structural changes in the virion that lead to the release of the lipid.

Incubation of poliovirus with PVR for short periods at low temperatures appears to result in loss of the lipid.⁵³ The results of computational modeling and kinetic studies suggest that stabilization of virus particles by drugs that replace the lipid is a consequence of increased compressibility rather than increased rigidity.^{395,470,500}

TRANSLATION OF THE VIRAL RNA

Internal Ribosome Binding: The Internal Ribosome Entry Site

Once the picornavirus positive-stranded genomic RNA is released into the cell cytoplasm, it must be translated because it cannot be copied by any cellular RNA polymerase and no viral enzymes are brought into the cell within the viral capsid. Several experimental findings led to the belief that translation of the picornavirus genome was accomplished by an unusual mechanism. The positive-stranded RNA genomes lack 5'-terminal cap

structures; although virion RNA is linked to the viral protein VPg, this protein is removed by a cellular unlinking enzyme on entry of the RNA into the cell.¹³ Furthermore, picornavirus genomes are efficiently translated in infected cells despite inhibition of cellular mRNA translation. Determination of the nucleotide sequence of poliovirus positive-stranded RNA revealed a 741-nucleotide 5'-untranslated region that contains seven AUG codons.^{276,415} Similar 5'-noncoding regions were subsequently found in other picornaviruses and shown to contain highly ordered RNA structures.^{426,461} These findings led to the suggestion that ribosomes do not scan through picornaviral 5'-untranslated regions, but rather bind to an internal sequence. The 5'-untranslated region of poliovirus positive-stranded RNA was subsequently shown to contain a sequence that promotes internal binding of the 40S ribosomal subunit; it was called the *internal ribosome entry site* (IRES) (Fig. 16.7).

All picornavirus RNA contain an IRES, as do other viral and some cellular mRNAs.³¹³ Viral IRES have been placed in four groups based on a variety of criteria, including primary

FIGURE 16.7. Discovery of the internal ribosome entry site (IRES). **A:** Bicistronic messenger RNA (mRNA) assay used to discover the IRES. Plasmids were constructed that encode two reporter molecules, thymidine kinase (tk) and chloramphenicol acetyl transferase (cat), separated by an IRES or a spacer. After introduction into mammalian cells, the plasmids give rise to mRNA of the structure shown in the figure. In uninfected cells (*top line*), both reporter molecules can be detected, although cat synthesis is inefficient without an IRES and is probably caused by reinitiation. In poliovirus-infected cells, 5' end-dependent initiation is inhibited, and no proteins are detected without an IRES, demonstrating internal ribosome binding. **B:** Circular mRNA assay for an IRES. Circular mRNA were constructed and translated *in vitro* in cell extracts. In the absence of an IRES, no protein is observed because 5'-end initiation requires a free 5' end. Inclusion of an IRES allows protein translation from the circular mRNA, demonstrating internal ribosome binding.

FIGURE 16.8. Four major types of picornaviral internal ribosome entry sites (IRES). The type I IRES is found in the genomes of enteroviruses. The genomes of cardioviruses and aphthoviruses contain a type II IRES. The IRES of hepatitis A virus is type III, and the type IV IRES is represented by porcine teschovirus 1; other picornaviruses with this type of IRES include simian virus 2, porcine enterovirus 8, simian picornavirus type 9, avian encephalomyelitis virus, and Seneca Valley virus.

sequence, secondary structure, location of the initiation codon, and activity in different cell types (Fig. 16.8). In the type I IRES (found in the genomes of enteroviruses and rhinoviruses), and the type III IRES (hepatitis A virus), the initiation codon is located 50 to 100 nucleotides beyond the 3'-end of the IRES, whereas it is located at the 3'-end of a type II IRES (cardioviruses and aphthoviruses). The IRES of porcine teschovirus, avian encephalomyelitis virus, and hepatitis C virus (a member of the *Flaviviridae*) are classified as a type IV IRES.

There is little nucleotide sequence conservation among different IRES elements. The picornavirus IRES contains extensive regions of RNA secondary structure (Fig. 16.7) that is not strictly conserved but is crucial for ribosome binding. One sequence motif that is conserved among picornavirus IRES is a GNRA sequence (G, guanine; N, any nucleotide; R, purine; A, adenine) in stem-loop IV of the type I IRES and in stem-loop I of the type II IRES. Another conserved element is an Yn-Xm-AUG motif, in which Yn is a pyrimidine-rich region and Xm is a 15- to 25-nucleotide spacer followed by an AUG codon. Translation initiation mediated by a type I IRES involves binding of the 40S ribosomal subunit to the IRES and scanning of the subunit to the AUG initiation codon. The 40S subunit probably binds at the AUG initiation codon of a type II IRES.

The type III IRES has little homology with type I and type II IRES except for the Yn-Xm-AUG motif. It is structurally distinct, consisting of two major domains, and in addition requires intact eIF4F complex.¹¹ The type IV IRES functions in a prokaryotic-like manner. The secondary structures of these RNA elements facilitate direct interaction with the small 40S ribosome.^{143,144,242,468} These interactions place a portion of the RNA within the P site of the 40S ribosomal subunit as observed by *in vitro* toeprinting and structural analyses of RNA-protein complexes. Initiation of translation mediated by the type IV IRES is therefore independent of all canonical translation proteins including the ternary complex of eIF2 α -GTP-met-tRNAi. The only initiation protein required is DHX29, necessary to unwind secondary structure surrounding the

initiation codon.^{401,546} No met-tRNAi is required, as the first amino acid of this polypeptide is glycine.²⁴²

The IRES of Aichi virus is distinct from types I, II, and III IRES and may represent a distinct class.⁵⁴⁶ Domain I is not related to elements found in any other IRES. Domain J consists of a long, interrupted basal helix and an apical four-way helical junction, similar to but smaller than domain IV in type I IRES. Its apical subdomain (Jb) also includes a GNRA tetraloop, which is essential for the function of type I and type II IRES. The apex of AV domain K contains an element identical to an apical motif in domain J of type II IRES that is essential for specific interaction with eIF4G.^{42,95} These domains are otherwise unrelated. An equivalent of domain K of type 2 IRES is also absent. Finally, the initiation codon is preceded by an Yn motif as in the type I/II IRES, but in contrast, it is sequestered in a long, stable hairpin, explaining why this IRES requires the DExH-box protein DHX29.

Mechanism of Internal Ribosome Binding

Different sets of translation initiation proteins are needed for internal initiation mediated by various IRES. Internal ribosome binding via the type III IRES requires all of the initiation proteins, including eIF4E. A subset of translation initiation proteins is required for the activity of most picornavirus IRES.

Translation initiation via a type I IRES involves binding of the 40S ribosomal subunit to the IRES, followed by scanning of the subunit to the initiation codon. The 40S subunit may bind directly to the RNA, or might be recruited to the IRES by interacting with translation initiation proteins. In cells infected with some picornaviruses, eIF4G is cleaved, inactivating the translation of most cellular mRNA. This observation led to the belief that eIF4G is not required for function of the IRES of poliovirus and other picornaviruses. The C-terminal fragment of eIF4G, which contains binding sites for eIF3 and eIF4A (Fig. 16.9), however, stimulates IRES-mediated translation.^{79,371} These findings have led to a model in which the 40S ribosomal subunit is recruited to the IRES through interaction with eIF3 bound to the C-terminal domain of eIF4G, which

5'-end dependent

IRES-dependent

FIGURE 16.9. Models for translation initiation complex formation. In 5′ end–dependent initiation, the 40S subunit is recruited to the messenger RNA (mRNA) through its interaction with eIF3, which binds eIF4G. The latter initiation factor is part of eIF4F, which also contains eIF4A, a helicase to unwind RNA secondary structure, and eIF4E, the cap-binding protein. Binding of eIF4E to the cap thus positions eIF4E at the 5′ end and positions the 40S subunit on the mRNA. In IRES-dependent translation, a 5′ end is not required. The eIF3–40S complex is believed to be recruited to the RNA by the interaction of eIF4G with the IRES.

binds directly to the IRES. Stimulation of IRES function by the C-terminal proteolytic fragment of eIF4G may explain the observation that IRES activity is enhanced in cells in which the poliovirus protease 2A^{pro} is expressed.²⁰⁰ Protease 2A^{pro} is one of the picornaviral proteinases responsible for cleavage of eIF4G. Although the IRES of most picornaviruses function with cleaved eIF4G, that of hepatitis A virus requires intact eIF4G.⁶⁹ The 40S ribosomal subunit binds at or near the AUG initiation codon of the type II IRES, and no scanning occurs.

The poliovirus IRES functions poorly in reticulocyte lysates, in which capped mRNA can be translated efficiently. Addition of a cytoplasmic extract to reticulocyte lysates restores efficient translation from this IRES. These observations led to the suggestion that ribosome binding to the IRES requires cell proteins other than the canonical translation proteins. Such proteins have been identified by their ability to bind the IRES and restore internal initiation in reticulocyte lysates (reviewed in¹³⁹). One host protein identified by this approach is the La protein, which binds to the 3′-end of the poliovirus IRES.³³¹ This protein is associated with the 3′-termini of newly synthesized small RNA, including transcripts of cellular RNA polymerase III. La protein is present in low amounts in reticulocyte lysates; addition of the protein to such lysates stimulates the activity of the poliovirus IRES.³³¹ La is a nuclear protein that is relocalized to the cytoplasm in poliovirus-infected cells.⁴⁵⁹ La protein is also required for efficient function of the encephalomyocarditis virus IRES.²⁷²

Polypyrimidine tract-binding protein (PTB) is composed of four RNA binding domains and functions as a regulator of pre-mRNA splicing. It binds the poliovirus IRES²¹¹ and is required by all type I IRES.²³⁰ Removal of this protein from a cell extract with an RNA affinity column inhibits the func-

tion of the FMDV IRES^{358,398} and that of encephalomyocarditis virus, but does not affect translation by 5′ end–dependent initiation.²⁵⁸ The deficiency in the function of these IRES is restored by adding the purified protein back to the lysate. The depleted lysate, however, still supports the function of the IRES from Theiler’s murine encephalomyocarditis virus, another picornavirus. It was subsequently shown that the requirement for polypyrimidine tract-binding protein by the encephalomyocarditis virus IRES depends on the nature of the reporter and the size of an A-rich bulge in the IRES.²⁵⁹ It is thought that PTB protein facilitates initiation via the type I IRES by modulating binding of eIF4G to the viral RNA through the interaction between the RNA-binding motifs 1 and 2 of PTB protein, the bottom of domain V of the type I IRES, and the RNA-binding motifs 3 and 4 within the single-stranded region of the viral RNA surrounding domain V of the IRES.²⁵⁷ Unlike the type I IRES, multiple copies of PTB protein are required to bind the FMDV, EMCV, and other type II IRES. RNA-binding domains 1 and 2 of one PTB molecule binds domain F of the IRES, and RNA-binding domains 3 and 4 bind domains D and E of the IRES. RNA-binding domains 1 and 2 of a second molecule of PTB bind domain K of the IRES, and RNA-binding domains 3 and 4 interact with IRES domains H, I, and L, all with lower affinity.²⁵⁶

HeLa cell extracts also contain unr, an RNA-binding protein with five cold-shock domains that is required for IRES function.²²⁹ Recombinant unr stimulates the function of the rhinovirus IRES in the reticulocyte lysate and acts synergistically with recombinant PTB protein to stimulate translation mediated by the rhinovirus IRES *in vitro*. However, the poliovirus IRES inefficiently mediates translation initiation in unr^{−/−} cells even though PTB is present.⁷³

Ribosome-associated poly r(C)-binding proteins bind at multiple sites within the poliovirus IRES.^{65,155} One binding site for these proteins has been identified within stem loop IV of the poliovirus IRES.⁶⁵ Mutations in this region that abolish binding of poly r(C)-binding proteins cause decreased translation *in vitro*. Furthermore, depletion of poly r(C)-binding proteins from HeLa cell translation extracts results in inhibition of poliovirus IRES function.⁶⁶ When this assay was used to survey a wide range of picornaviral IRES elements, it was found that poly r(C)-binding proteins are required for function of the type I, but not the type II, IRES.⁵¹⁸ A second binding site for poly r(C)-binding proteins has been identified within a cloverleaf RNA structure that forms within the first 108 nucleotides of the positive-stranded poliovirus RNA genome.^{155,377} The interaction of poly r(C)-binding proteins with this part of the RNA has been proposed to regulate whether a positive-stranded RNA molecule is translated or replicated.

The nuclear-cytoplasmic protein SRp20 functions with poly r(C)-binding protein 2 to promote initiation on poliovirus mRNA.⁵⁰ SRp20 binds to the KH3 domain of poly r(C)-binding protein 2. Depletion of SRp20 from cellular lysates by monoclonal antibodies or from cells by short interfering RNAs reduced IRES-mediated translation by 50%. Polysome analysis of infected cells by sucrose gradient fractionation demonstrated that both SRp20 and poly r(C)-binding protein 2 are at least partly associated with translation initiation complexes bound to stem loop V of the poliovirus 5'-UTR.¹⁴⁰

Murine proliferation-associated protein 1 (Mpp-1) is required for the function of the foot-and-mouth disease virus IRES. This protein binds to a central domain of the viral IRES and acts synergistically with polypyrimidine tract-binding protein to increase the binding of eIF4E. It has been suggested that Mpp-1 may determine the tissues in which the IRES functions. To test this hypothesis, a recombinant virus was constructed by replacing the IRES of Theiler's virus with that of FMDV. Theiler's virus replicates in the mouse brain, but the recombinant virus cannot, possibly because of the absence of Mpp-1 in this organ.³⁹⁸

The DEXH-box helicase DHX29 is necessary for the activity of the Aichi virus IRES.⁵⁴⁶ Initially this protein was identified because it enabled efficient 48S complex formation on cellular mRNAs possessing highly structured 5'UTRs.⁴⁰¹ It is believed to be required for proper placement of the ribosome on RNAs possessing prokaryotic-like IRES elements, such as those of classic swine fever virus and the intergenic IRES of CrPV.⁴⁰¹

No single cellular protein has been identified that is essential for the function of all viral IRES. A common property of cellular proteins needed for IRES activity is that they are RNA-binding proteins that can form multimers with the potential to contact the IRES at multiple points. This observation has led to the hypothesis that such proteins may act as RNA chaperones, maintaining the IRES in a structure that permits it to bind directly to the translational machinery.²³⁵ IRES that do not require such chaperones may fold properly without the need for cellular proteins.

Processing of the Viral Polyprotein

Picornavirus proteins are synthesized by the translation of a single, long, ORF encoded by the viral positive-stranded RNA genome, followed by cleavage of the polyprotein by virus-

encoded proteinases (Figs. 16.3 and 16.10). This strategy allows the synthesis of multiple protein products from a single RNA genome. The polyprotein is not observed in infected cells because it is processed as soon as the protease coding sequences have been translated. The polyprotein precursor is processed cotranslationally by intramolecular reactions (in *cis*) in what are called *primary cleavages*, followed by secondary processing in *cis* or in *trans* (intermolecular). All picornavirus genomes encode at least one proteinase, 3C^{pro}/3CD^{pro}, and some encode L^{pro} or 2A^{pro}.

The first protein encoded in the genome of aphthoviruses, cardioviruses, and erboviruses is the L protein (Figs. 16.3 and 16.10). The L protein of aphthoviruses and erboviruses is a proteinase that releases itself from the polyprotein by cleaving between its C-terminus and the N-terminus of VP4.^{217,475} Based on sequence analysis, it was suggested that FMDV L^{pro} is related to thiol proteases.¹⁷⁸ This prediction was supported by the results of site-directed mutagenesis, which showed that Cys-51 and His-148 are the active-site amino acids.^{396,427} The atomic structure of L^{pro} reveals that it consists of two domains, with a topology related to that of papain, a thiol proteinase¹⁸⁹ (Fig. 16.11). The active-site His is located at the top of the central α -helix, and substrate binds in the groove between the two domains. Besides releasing itself from the polyprotein, L^{pro} also cleaves the translation initiation factor eIF4G, causing inhibition of cellular translation.¹¹⁹ The cardiovirus L protein, which does not have proteolytic activity, is released from the P1 precursor by 3C^{pro}.³⁷⁴

In cells infected with enteroviruses (and possibly sapeloviruses), the primary cleavage between P1 and P2 is mediated by 2A^{pro}. Cellular proteins are also cleaved by 2A^{pro}, including eIF4GI, eIF4GII, Pabp, heart muscle dystrophin, and nucleoporins.^{27,86,180,181,191,192,247,268,286,375} In the protein precursor of rhinovirus, poliovirus, and some other enteroviruses, the cleavage site for 2A^{pro} is between tyrosine and glycine. Other sites cleaved by 2A^{pro} include threonine-glycine and phenylalanine-glycine in certain Cocksackieviruses and echoviruses. Based on sequence alignments, it was suggested that the structure of 2A^{pro} would resemble that of small bacterial chymotrypsin-like proteinases (e.g., *Streptomyces griseus* proteinase A) and would possess a catalytic triad consisting of His-20, Asp-38, and an active-site nucleophile of Cys-109 rather than serine.⁴⁸ The results of site-directed mutagenesis and the resolution of the atomic structure of rhinovirus and Cocksackievirus B4 2A^{pro} confirm that these residues comprise the active site and that the fold of 2A^{pro} is very similar to that of *Streptomyces griseus* proteinase A.^{45,388,467,545} (Fig. 16.11). However, 2A^{pro} differs from all known chymotrypsin-like proteinases in that the N-terminal domain is not a β -barrel, but rather a four-stranded antiparallel β -sheet. The larger C-terminal domain contains a six-stranded antiparallel β -barrel. The active-site catalytic triad is located in a cleft between the two domains. Another unusual feature of 2A^{pro} is a tightly bound zinc ion located at the beginning of the C-terminal domain. Biochemical and structural studies indicate that zinc is essential for the structure of the enzyme.^{388,466,516}

The 2A/2B junction of aphthoviruses, avihepatoviruses, cardioviruses, erboviruses, senecaviruses, teschoviruses, Ljungan virus and duck hepatitis virus is cleaved not by proteolysis but by an unusual mechanism called ribosomal skipping.¹²⁶ Changes within the conserved amino acid sequence Asn-Pro-Gly-Pro,

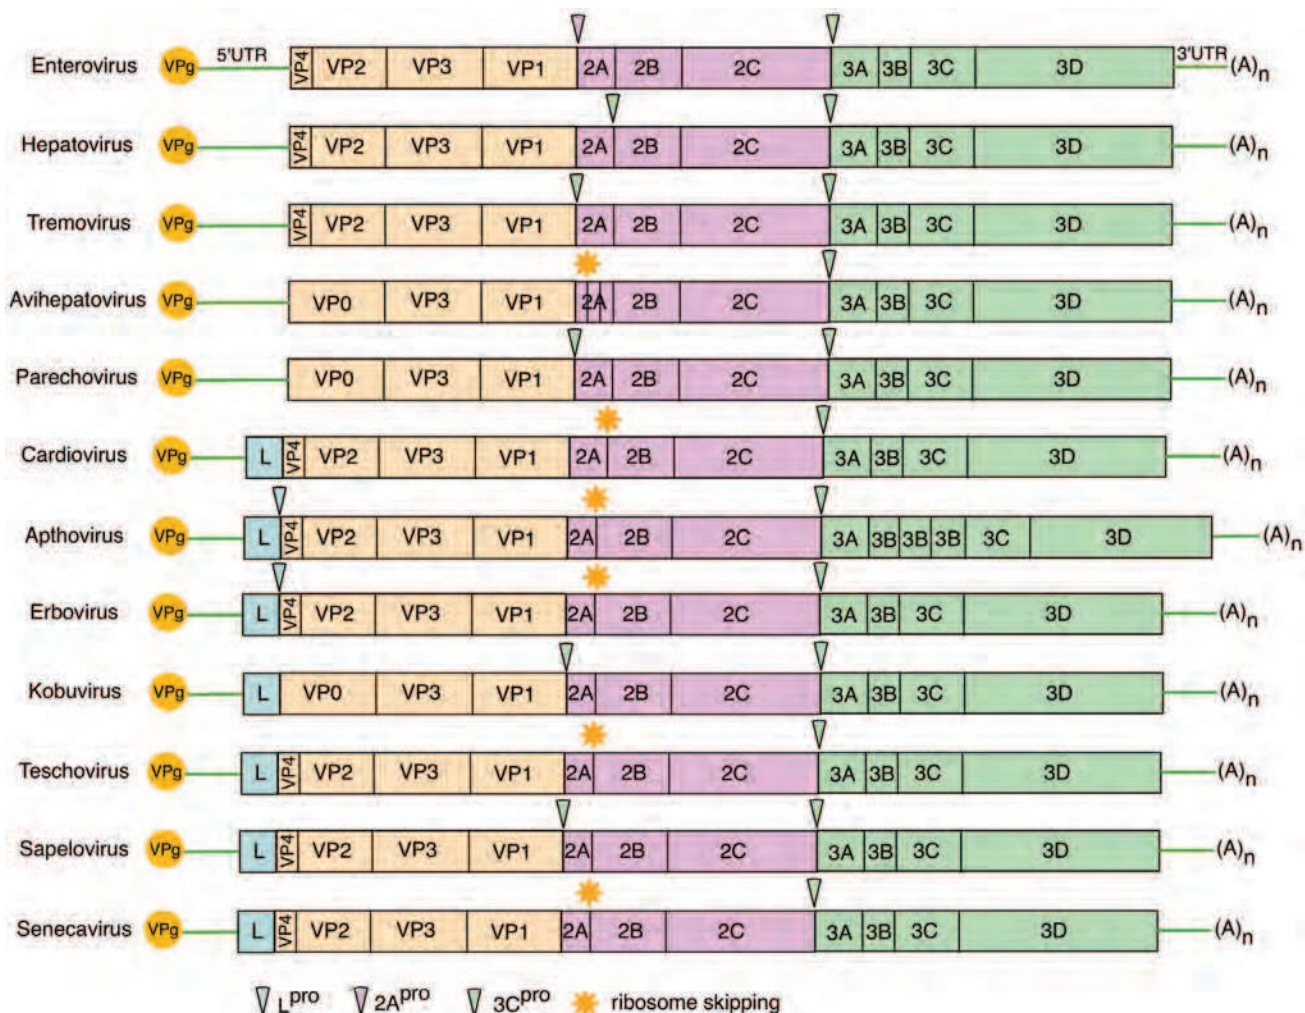

FIGURE 16.10. Primary cleavages of picornavirus polyprotein. In all viruses shown, the P2–P3 cleavage is carried out by 3C^{pro} (green triangle). In some picornaviruses, the P1–P2 cleavage is carried out by 2A^{pro} (magenta triangle) or 3C^{pro}; in others, the 2A/2B bond is separated by ribosome skipping (orange asterisk). The L^{pro} proteinase (blue triangle) of aphthoviruses and erboviruses catalyzes its release from VP4.

FIGURE 16.11. Three-dimensional structures of L^{pro} of foot-and-mouth disease virus, rhinovirus 2A^{pro}, and hepatitis A virus 3C^{pro}. Below each is the cellular proteinase that is structurally similar to each viral enzyme. Catalytic residues are drawn as *balls and sticks*. Images drawn with MacPyMol using the following pdb files: 2sga, 2hrv, 2jqg, 1pip, 1hav, 5cha.

which contains the cleavage site Gly-Pro, disrupt cleavage.³⁷⁴ The mechanism of NPG/P-mediated cleavage is not understood. It has been suggested that aphthovirus and cardiovirus 2A might modify the ribosome, causing the translational machinery to skip the synthesis of a glycyl-prolyl peptide bond at the C-terminus of 2A.¹²⁷ If this model is correct, it would represent a novel mechanism for the release of proteins from a polyprotein precursor without enzymatic cleavage. Similar 2A-like sequences have been found in other viral genomes and trypanosome non-LTR retrotransposons.³¹⁰ The ability of the 2A sequence to yield two proteins from a single open reading frame, without proteinase activity, has led to its use in many research and biomedical applications.⁴³⁸

Because only enteroviruses and possibly sapeloviruses have proteolytically active 2A^{pro}, in cells infected with other picornaviruses, the VP1–2A cleavage is either carried out by 3C^{pro}^{245,374,448,449} or in Ljungan virus by an NPG/P sequence following the VP1 protein²⁴⁹ (Fig. 16.10).

The polyprotein of Aichi virus, a member of the *Kobuvirus* genus, is unusual because the L and 2A proteins are not proteinases and there is no NPG/P motif at the 2A/2B junction. The only active proteinase encoded in the genome of this virus is 3C^{pro} and 3CD^{pro}, which can process all cleavage sites in the polyprotein, including the VP1/2A site.⁴⁴⁵ Efficient cleavage of the VP1/2A site requires tight binding of 3CD to the 2A region of the substrate.

All picornaviruses encode 3C^{pro}, which carries out a primary cleavage between 2C and 3A (Fig. 16.10). Unlike the other picornavirus proteinases, 3C^{pro} also carries out secondary cleavages of the P1 and P2 precursors. Poliovirus 3C^{pro} cleaves only at the Gln-Gly dipeptide; however, 3C^{pro} of other picornaviruses has less strict cleavage specificities and cleaves at other sites, including Gln-Ser, Gln-Ile, Gln-Asn, Gln-Ala, Gln-Thr, and Gln-Val. Clearly, other determinants of cleavage exist because not all such dipeptides in picornavirus polyproteins are cleaved by 3C^{pro}. Additional determinants include accessibility of the cleavage site to the enzyme, recognition of secondary and tertiary structures in the substrate by the enzyme, and amino acid sequences surrounding the cleavage site. For example, efficient cleavage of poliovirus Gln-Gly pairs requires an Ala at the P4 position (Gln is residue P1, numbering is toward the N-terminus).⁶⁴

Sequence comparisons with cellular proteinases led to the prediction that 3C^{pro} folds similarly to the chymotrypsin-like serine proteinases, in particular *Staphylococcus aureus* proteinase.^{48,174–177} The putative catalytic triad was believed to consist of His-40, Asp-71 (aphthoviruses and cardioviruses) or Glu-71 (enteroviruses and rhinoviruses), and Cys-147 as the nucleophilic residue, in contrast to serine in cellular serine proteinases. These predictions have been confirmed by site-directed mutagenesis and by resolution of the atomic structures of rhinovirus, hepatitis A virus, poliovirus, FMDV, and enterovirus 71 3C^{pro}.^{89,186,201,267,323,346,388,519} The viral enzyme folds into two equivalent β -barrels like chymotrypsin (Fig. 16.11), but differs in some of the connecting loops, the orientation of the catalytic residues, and in areas needed for transition-state stabilization. The acidic member of the catalytic triad, Glu or Asp, points away from the active-site His and, therefore, is not believed to assist in catalysis. However, 3C^{pro} also binds viral RNA (see discussion of genome replication and mRNA synthesis), and this binding site is distal from the active site of the enzyme.

The presence of this RNA-binding site imposes evolutionary constraints on 3C^{pro} that are not found in other proteinases.

Both 3C^{pro} and 2A^{pro} are active in the nascent polypeptide and release themselves from the polyprotein by self-cleavage. After the proteinases have been released, they cleave the polyprotein in *trans*. The cascade of processing events varies for different picornaviruses. In cells infected with rhinovirus and enteroviruses, the initial event in the processing cascade is the release of the P1 precursor from the nascent P2–P3 protein by 2A^{pro}. The activity of 2A^{pro} does not depend on whether it is cleaved from the precursor,²¹⁰ but further processing of P1 by 3CD^{pro} does not occur unless 2A^{pro} is released from P1.^{357,543} Next, 3CD^{pro} is released from the P3 precursor by autocatalytic cleavage. This proteinase, which contains the entire sequence of the viral RNA polymerase, carries out secondary cleavage of glutamine-glycine dipeptides in poliovirus P1 far more efficiently than 3C^{pro}.^{253,544} Both 3C^{pro} and 3CD^{pro} process proteins of the P2 and P3 regions with similar efficiency. The 3D^{pol} sequence within 3CD^{pro} may be required to recognize structural motifs in properly folded P1, allowing efficient processing by the 3C^{pro} part of the enzyme. The presence of multiple activities in a single protein is not found among eukaryotic proteinases and is an example of how the coding capacity of small viral genomes can be maximized. Not all picornaviruses require 3CD^{pro} to process P1; aphthoviruses, cardioviruses, and hepatoviruses produce 3C^{pro} that can cleave P1 without additional viral protein sequence.

An advantage of the polyprotein strategy is that expression can be controlled by the rate and extent of proteolytic processing. Alternative use of cleavage sites can also produce proteins with different activities. For example, because 3CD^{pro} is required for processing of the poliovirus capsid protein precursor P1, the extent of capsid protein processing can be controlled by regulating the amount of 3CD^{pro} that is produced. Because 3CD^{pro} does not possess RNA polymerase activity, some of it must be cleaved to allow RNA replication.

A final processing step occurs during maturation, when VP0 is cleaved to form VP4 and VP2. This event is discussed later.

VIRAL RNA SYNTHESIS

In the 1950s, it was believed that the genome of RNA viruses was replicated by the cellular DNA-dependent RNA polymerase, through an intermediate DNA strand. The replication of RNA viruses, therefore, was thought to occur entirely in the cell nucleus. In the early 1960s, studies of mengovirus showed that virus infection results in the induction of a cytoplasmic enzyme that can synthesize viral RNA in the presence of actinomycin D.³⁰ This observation suggested that viral genome replication occurred through a virus-specific, RNA-dependent RNA polymerase because cellular RNA synthesis is DNA dependent; it occurs in the nucleus and is sensitive to actinomycin D. A similar cytoplasmic, actinomycin D-resistant genome replication system was discovered in poliovirus-infected cells.²⁸

In poliovirus-infected cells, the positive-stranded genome is amplified to about 50,000 copies per cell through a negative-stranded intermediate. Three forms of viral RNA have been identified in the cell; single-stranded RNA, replicative intermediate (RI), and replicative form (RF). Single-stranded RNA,

the most abundant form, is exclusively positive stranded; free negative strands have never been detected in infected cells. RI is full-length RNA from which six to eight nascent strands are attached. RI is largely of positive polarity with nascent negative strands, although the opposite configuration has been detected. RF is a double-stranded structure, consisting of one full-length copy of the positive and negative strands. Viral RNA synthesis is asymmetric; the synthesis of positive strands is 30 to 70 times greater than the synthesis of negative strands.^{162,364}

Viral RNA-Dependent RNA Polymerase, 3D^{pol}

The first evidence for a viral RNA-dependent RNA polymerase activity came from experiments in which lysates from cells infected with mengovirus or poliovirus were assayed for viral RNA polymerase activity by the incorporation of a radioactive nucleotide into viral RNA.²⁹ Initial experiments demonstrated that the viral RNA polymerase is associated with a cellular membrane fraction, subsequently shown to be comprised of smooth membranes, which was called the *RNA replication complex*.¹⁶⁶ A major component of the replication complex was a viral protein that migrated at 63,000 d on polyacrylamide gels (therefore, called p63), which was suggested to be the viral RNA-dependent RNA polymerase. Other viral and host proteins, including 2BC, 2C, 3AB, and 3C^{pro}, however, were detected in the RNA replication complexes.

A limitation of this early work was that replication complexes only copied viral RNA already present in the complex, and did not respond to added RNA. Attempts were made, therefore, to purify a template-dependent enzyme from membrane fractions of infected cells, using a poly(A) template and an oligo(U) primer. A poly(U) polymerase activity was purified from poliovirus-infected cells, which could also copy poliovirus RNA in the presence of an oligo(U) primer. Highly purified preparations contained only p63, the major viral protein found in membranous replication complexes.^{141,504} This protein is the poliovirus RNA polymerase, now known as 3D^{pol}. In the absence of an oligo(U) primer, 3D^{pol} cannot copy poliovirus RNA. Recombinant 3D^{pol} purified from bacteria or insect cells also requires the presence of an oligo(U) primer to copy poliovirus RNA.^{354,404} 3D^{pol}, therefore, is a template- and primer-dependent enzyme that can copy poliovirus RNA. Its molecular weight predicted from the amino acid sequence is 53 kd.

The structures of three of the four types of polymerases—DNA-dependent DNA polymerase, DNA-dependent RNA polymerase, and RNA-dependent DNA polymerase (reverse transcriptase)—are characterized by analogy with a right hand, consisting of a palm, fingers, and thumb. The palm domain contains the active site of the enzyme. The first structure of an RNA-dependent RNA polymerase is that of poliovirus 3D^{pol}, first determined at 2.6 Å resolution by x-ray crystallography.²⁰² Additional structures of 3D^{pol} from poliovirus, three rhinovirus serotypes, and coxsackievirus B3 provide resolution of virtually all amino acids in the protein, offering a complete picture of the enzyme.^{22,81,307,488} The enzyme has the same overall shape as other polymerases, although the fingers and thumb differ (Fig. 16.12). The fingers and thumb domains interact, resulting in an encircled active site. The palm domain contains four conserved amino acid motifs (B, C, D, E) that are found in other RNA-dependent polymerases. Amino acids 1 to 68 (forming the ring finger) cross the active site under the index finger and

extend to the enzyme surface. The ring finger, which is the top of the channel through which nucleoside triphosphates enter, includes conserved motif F that is important for interacting with the triphosphates. Template and primer molecules that contact the front face of 3D^{pol} probably use the opening for nucleotide exchange, as do other polymerases. A template RNA channel in the fingers domain of all the picornavirus polymerases is lined with basic amino acids that are predicted to interact with viral template as it enters the active site. Alteration of amino acids in this channel identifies key residues for template binding or elongation.²⁸⁴

The RNA polymerase 3D^{pol} is produced by cleavage of a precursor protein, 3CD^{pro}, which is highly active as a proteinase, binds *cre* (see below), but has no polymerase activity. It was suggested that processing of 3CD affected the location of the N-terminus of 3D^{pol}, which is buried in a surface pocket in 3D^{pol}. There it makes hydrogen bonds that position Asp238, an essential residue that selects for the 2' OH group of substrate rNTP (ribonucleoside triphosphate), in the active site. On proteolysis, the N-terminal Gly was believed to push Asp-238 a distance of 1.4 Å into the catalytic site. However, a comparison of structures of 3D^{pol} and 3CD^{pro} did not show a significant difference in the position of Asp238.^{317,488} Resolution of the structure of the coxsackievirus B3 3D^{pol} reveals an unusual conformation for residue 5, which is located at a distortion within a β-strand that is conserved in all known 3D^{pol} structures.⁸¹ Substitution of more hydrophobic residues at this position results in higher enzymatic activity. It has been proposed that this residue becomes buried during the repositioning of the nucleotide that takes place before phosphoryl transfer, which cannot occur if the N-terminus has not been properly generated by proteolytic processing.

The first poliovirus 3D^{pol} structure revealed that the polymerase molecules interacted in a head-to-tail manner and formed fibers; subsequently, the protein was shown to form a lattice.³¹¹ The implication was that RNA would be replicated as it moved along the lattice, rather than the polymerase moving on the template. The head-to-tail fibers were formed by interface I, which involves more than 23 amino acid side chains between the thumb of one polymerase and the back of the palm of another (Fig. 16.13). Amino acid changes in the back of the thumb that disrupt this interface impaired replication.^{120,221} Repetition of this interaction in a head-to-tail fashion results in long fibers of polymerase molecules 50 Å in diameter. A similar interface was observed in crystals of 3D^{pol} of rhinovirus 14 but not rhinoviruses 16 or 1b.³⁰⁷ Interface II is formed by N-terminal polypeptide segments, which may lead to a network of polymerase fibers in combination with interactions at interface I. These N-terminal polypeptide segments may originate from different polymerase molecules. The N-terminus of 3D^{pol} is required for enzyme activity, which would support the idea that interface II interactions are of functional consequence. Furthermore, intermolecular cross-linking has been observed between cysteines engineered at Ala-29 and Ile-441 of poliovirus 3D^{pol}²²¹ and disruption of these interactions led to lethality.⁴⁸⁶ Polymerase-containing oligomeric structures resembling those seen with purified 3D^{pol} were observed on the surface of vesicles isolated from poliovirus-infected cells.³¹¹ Because picornavirus RNA synthesis occurs on membranous vesicles, the concept of a flat, catalytic lattice is mechanistically attractive.

FIGURE 16.12. Three-dimensional structure of poliovirus 3D^{pol}. Structure of poliovirus 3D^{pol} polymerase and its elongation complex with primer-template RNA. The polymerase structure can be described by analogy to a cupped right hand, consisting of palm (gray) and thumb (blue) domains and a fingers domains with four discrete structural elements known as the index (green), middle (orange), ring (yellow), and pinky (red) fingers. The structure of the elongation complex shows the path of the RNA as the template strand (cyan) enters the polymerase from the top and of the template-product (gold) duplex as it exits the polymerase between the pinky finger and thumb structures.²²⁰ **A-C:** Views from the top of the polymerase looking down into the active site (magenta) of 3D^{pol} in the absence of RNA (**A**), the 3D^{pol} elongation complex with bound RNA (**B**), and the elongation complex with a surface representation of the polymerase to show how the product RNA duplex is clamped in place between the pinky finger and thumb structures (**C**). **D:** Front view of the elongation complex showing the path template and product RNA strands. **E:** Back view of the elongation complex showing the NTP entry channel with the priming 3' OH (red sphere) positioned above the active site and a bound di-deoxy-CTP (green ball-and-stick with phosphate groups in red and yellow). **F:** Surface representation of the elongation complex looking down the axis of the exiting RNA duplex. 3D^{pol} from poliovirus and closely related picornaviruses is activated upon cleavage from the viral polyprotein, resulting in a newly created N-terminus that becomes buried in a pocket at the base of the finger domain that is ≈15 Å away from the active site itself (blue sphere in **A** and **E**). (Courtesy of Olve Peersen, Colorado State University.)

FIGURE 16.13. Model for the synthesis of poliovirus (–) strand RNA. The (+) strand template is shown in green with the 5'-cloverleaf structure, the internal *cre* sequence, and the 3' pseudoknot. A ribonucleoprotein complex is formed when poly r(C)-binding protein (PCBP) and 3CD^{pro} bind the cloverleaf structure. The ribonucleoprotein complex interacts with PABP1, which is bound to the 3'-poly(A) sequence, producing a circular template. Protease 3CD^{pro} cleaves membrane-bound 3AB to produce VPg and 3A. The *cre* sequence binds 3D^{pol}, 3CD^{pro}, and VPg. VPg-pUpU is synthesized by 3D^{pol} using the sequence AAACA of *cre* as template. The complex is transferred to the 3' end of the genome, and 3D^{pol} uses VPg-pUpU to prime RNA synthesis.

Viral Accessory Proteins

The poliovirus capsid proteins are not required for viral RNA synthesis; the region of the viral genome that encodes these proteins can be deleted without affecting the ability of viral RNA to replicate in cells.²⁶⁰ The capsid coding regions of rhinovirus, Theiler's virus, and Mengovirus, however, contain a *cis*-acting RNA sequence required for genome replication.^{304,328,329} A *cis*-acting RNA sequence required for RNA replication has also been identified in the poliovirus protein 2C coding region.¹⁷¹ Genetic and biochemical studies implicate most proteins of the P2 and P3 regions of the genome in RNA synthesis.

2A Protein

As discussed above, 2A^{pro} protein is necessary for proteolytic cleavage of the polyprotein. The protein also appears to have a role in RNA replication. A deletion within the 2A^{pro} coding sequence severely inhibits replication of subgenomic replicons, which lack the capsid region and are not dependent on proteolytic activity of 2A^{pro} to release the P1 region.⁹⁸ In another approach, a second IRES element was placed in the poliovirus genome before the 2A^{pro} coding region, effectively alleviating the need for the processing activity of the enzyme. Such viruses are viable.³³⁹ Deletion of part of the coding region for 2A^{pro} is lethal, however. These results suggest that 2A^{pro} also plays a role in viral RNA replication. By using a cell-free replication system, it was possible to determine the effect of 2A^{pro} on each step of the replication cycle.²⁵⁵ The results show that 2A^{pro} stimulates the initiation of negative-strand synthesis, but has no effect on positive-strand synthesis. How 2A^{pro} achieves this affect is not known, but it has been suggested that the proteinase might modify a cellular protein required for negative-strand RNA synthesis.²⁵⁵

2B Protein

The 2B protein is a small, hydrophobic, membrane-associated protein that is involved at an early step of viral RNA synthesis. Alterations of the 2B protein of poliovirus and coxsackievirus lead to viruses with defects in RNA synthesis.^{251,505} Adaptation of rhinoviruses to mouse cells is mediated in part by amino acid changes in 2B, which allow viral RNA synthesis in this host cell.²⁰⁶ The C-terminus of 2B contains a hydrophobic region and a conserved putative amphipathic α -helix that appear to be crucial to the function of the protein and its association with membranes.⁵⁰⁶ Protein 2B has been called a *viroporin*, a protein that oligomerizes and inserts into membranes to create channels.^{2,170} The exact role of 2B in RNA synthesis, however, is not known. Synthesis of protein 2B leads to an inhibition of protein secretion from the Golgi apparatus^{35,123} and permeabilization of membranes,^{2,7,444,508,509} which may play a role in release of virus from cells. Protein 2B is also partly responsible for the proliferation of membranous vesicles in infected cells, which are the sites of viral RNA replication. Because protein 3A has the same effect, it is not clear whether altered membrane proliferation is responsible for the RNA-defective phenotype in 2B mutants.

2C Protein

Protein 2C is a highly conserved protein with membrane-, RNA-, and NTP-binding regions.^{131,429,430,508,509} The structure of 2C suggests that it contains three domains, with amphipathic α -helices at both the N- and C-termini that mediate peripheral association with membranes^{285,487} and a central

region with NTP-binding domains. Mutations responsible for resistance of poliovirus and echovirus to guanidine hydrochloride, which blocks viral RNA replication, are located in the 2C protein.^{278,399} This compound has been shown to inhibit specifically the initiation of negative-stranded RNA synthesis and has no effect on initiation of positive-stranded RNA synthesis or on elongation on either strand.⁴⁰ The nucleoside triphosphatase (NTPase) activity of protein 2C is inhibited by guanidine.³⁹⁴ Protein 2C shares amino acid homology with known RNA helicases, proteins encoded by most positive-stranded RNA viruses with large genomes. These enzymes are believed to be necessary to unwind double-stranded RNA structures that form during RNA replication. Purified protein 2C, however, does not have RNA helicase activity.⁴²⁹ Alteration of conserved amino acids within the NTPase domain of 2C results in loss of viral infectivity; 2C, therefore, may have two functions during viral RNA synthesis: as an NTPase and directing replication complexes to cell membranes. Synthesis of 2C causes disassembly of the Golgi apparatus and endoplasmic reticulum (ER), and formation of vesicular structures similar, but not identical to, those that constitute the replication complex.^{6,92}

2BC Protein

Much of protein 2BC, the precursor to 2B and 2C, remains uncleaved during infection, and its presence is critical to viral replication.⁹² Synthesis of 2BC causes membrane permeabilization to a greater degree than 2B synthesis alone,⁷ and leads to the formation of vesicles that are more similar to those formed during viral infection than does protein 2C.^{6,92} The C-terminus of 2B and the N-terminus of 2C may interact intramolecularly in 2BC, and protein cleavage may cause a conformational change that alters the properties of 2B and 2C individually.^{35,507} Larger 2BC-containing precursors are also required for certain steps of replication,²⁵⁴ although an intact 2C–3A junction is not strictly required.³⁸⁰

3AB Protein

A strongly hydrophobic region in the C-terminus of 3A mediates the association of 3A and its precursor, 3AB, with membranes.^{124,474,495} Amino acid changes in the hydrophobic region of 3A yield replication-defective viruses.^{163,287} Changes in viral host range have been mapped to changes in 3A protein.^{49,206,287,365} The solution structure of 3A demonstrates that it is a homodimer, with the dimer interface located in the central region of the protein.⁴⁷⁴ The requirement for 3A dimerization during infection has not been explored. Protein 3B, also known as VPg, plays an indispensable role in viral replication by acting as a protein primer for viral RNA synthesis (see below). Protein 3AB is believed to anchor VPg in membranes for the priming step of RNA synthesis. The purified protein greatly stimulates 3D^{pol} activity *in vitro*^{379,405,424} as well as the proteolytic activity of 3CD^{pro}.³⁴⁰ 3AB interacts with 3D^{pol} and 3CD^{pro} in infected cells and with 3D^{pol} in the yeast two-hybrid system.²²⁶ Amino acid changes in 3D^{pol} that disrupt its interaction with 3AB result in viruses with defects in protein processing and viral RNA synthesis.^{161,163} A complex of 3AB and 3CD^{pro} also binds the 3'-terminal sequence of poliovirus RNA.

Cellular Accessory Proteins

Early studies of poliovirus replication using purified components suggested that a host cell protein is required for copying

the viral RNA by 3D^{pol} in the absence of an oligo(U) primer.¹¹⁶ Although this protein was never identified, the concept of a host factor required for poliovirus replication endured, largely because an ample precedent was seen for the participation of host cell components in a viral RNA replicase. The best-studied example is the RNA replicase of the bacteriophage Q β , which is a multisubunit enzyme consisting of a 65-kd virus-encoded protein and three host proteins: ribosomal protein S1 and translation factors EF-Tu and EF-Ts.²⁰³ The 65-kd viral protein has no RNA polymerase activity in the absence of the host factors but has sequence similarity with known RNA-dependent RNA polymerases. A subunit of the translation initiation factor eIF-3 is part of the polymerase from brome mosaic virus.⁴¹² Two different experimental systems have been used to provide additional evidence that poliovirus RNA synthesis requires host cell components.

When purified poliovirus RNA is incubated *in vitro* with a cytoplasmic extract prepared from cultured, permissive cells, the viral RNA is translated, the resulting protein is proteolytically processed, and the genome is replicated and assembled into new infectious virus particles.³³⁸ When guanidine, an inhibitor of poliovirus RNA synthesis, is included in the reaction, complexes are formed, but elongation cannot occur.³⁸ The preinitiation complexes can be isolated free of guanidine and, when added to new cytoplasmic extracts, RNA synthesis occurs. In the absence of cytoplasmic extract, preinitiation complexes do not synthesize viral RNA.³⁷ These results indicate that one or more soluble cellular components are required for the initiation of viral RNA replication. A similar conclusion comes from studies in which poliovirus RNA is injected into oocytes derived from the African clawed toad, *Xenopus laevis*. Poliovirus RNA cannot replicate in *Xenopus* oocytes unless it is coinjected with a cytoplasmic extract from human cells.¹⁵⁴

Cellular poly r(C)-binding proteins are required for poliovirus RNA synthesis. These proteins bind to a cloverleaf-like secondary structure, also called a stem-loop I, that forms in the first 108 nucleotides of positive-stranded RNA (Fig. 16.13). Binding of poly r(C)-binding protein to the cloverleaf is necessary for the binding of viral protein 3CD^{pro} to the opposite side of the same cloverleaf.^{16,18,155,377} Formation of a ribonucleoprotein complex composed of the 5' cloverleaf, 3CD^{pro}, and a cellular protein is essential for the initiation of viral RNA synthesis.¹⁸ The human cell protein required for replication of poliovirus RNA in *Xenopus* oocytes has also been identified as poly r(C)-binding protein.¹⁵⁵ A model of how these interactions lead to viral RNA synthesis is shown in Figure 16.14. The ternary complex with stem-loop I may also function during positive-strand RNA synthesis.⁵¹⁵

Another candidate for a host protein that is essential for poliovirus RNA synthesis is poly(A)-binding protein 1. This protein interacts with poly r(C)-binding protein, 3CD^{pro}, and the 3'-poly(A) tail of poliovirus RNA, circularizing the genome^{40,212} (Fig. 16.13). Formation of this circular ribonucleoprotein complex is required for negative-strand RNA synthesis.

Protein-Primed RNA Synthesis

As discussed, poliovirus 3D^{pol} is a primer-dependent enzyme that will not copy poliovirus RNA *in vitro* without an oligo(U) primer. The discovery of VPg linked to poliovirus genome RNA, as well as to the 5' end of newly synthesized positive-

FIGURE 16.14. Schematic diagram of RNA recombination in picornavirus-infected cells by template switching, or copy choice.

Two parental genomes, the acceptor and donor, are shown. The RNA polymerase (blue) is shown copying the 3' end of donor RNA and switching to the acceptor genome (middle). As a result of this template switch, the recombinant RNA shown is formed (bottom).

and negative-stranded RNA, suggested that VPg might be involved in the initiation of RNA synthesis. This hypothesis was supported by the finding that both VPg and a uridylylated form of the protein, VPg-pUpU, can be found in infected cells.¹¹⁰ Furthermore, VPg-pUpU can be synthesized *in vitro* in a membrane fraction from poliovirus-infected cells.⁴⁸¹ It was also argued that a precursor of VPg, known as 3AB, is likely to participate in the initiation reaction. 3AB is a membrane-bound polypeptide and, therefore, an ideal candidate to act as a VPg donor in membranous replication complexes. Viruses containing a mutation in 3AB that decreases its hydrophobicity are defective in initiation of RNA synthesis, *in vitro* uridylation of VPg, and *in vivo* synthesis of positive-stranded viral RNA.^{161,163} Because no protein larger than VPg has been detected linked to nascent RNA strands, it is likely that 3AB is rapidly cleaved by the proteinase 3C^{pro} to form VPg-linked RNA. Additional evidence that VPg can serve as a primer for poliovirus RNA synthesis comes from experiments in which synthetic VPg is first uridylylated *in vitro*, then added to an *in vitro* polymerase reaction containing a poly(A) template and 3D^{pol}.³⁸¹ The labeled, uridylylated VPg is extended to form poly(U). Poliovirus RNA replication is primed by a genome-linked protein, a mechanism also involved in adenovirus DNA replication. A model for VPg priming of poliovirus RNA synthesis is shown in Figure 16.13.

The template for uridylation of VPg is an RNA hairpin, the *cis*-acting replication element, *cre*, located in the coding

region of picornaviruses.^{382,425,540} The cre functions independent of position in the genome, and its location differs among viruses. Protein 3C is a major determinant of RNA binding activity, but 3AB may also be involved in cre recognition.^{378,533} Whether cre-dependent VPg uridylation is involved only in (+) strand RNA synthesis, or also during synthesis of the (–) strand, is controversial.^{173,341,350,425}

The results of genetic analyses indicate that the binding site for VPg (as part of 3AB) on 3D^{pol} is on the surface of the enzyme near conserved motif E, on the back side of the palm near the base of the thumb, which is distant from the catalytic center.³¹² Because uridylation of VPg takes place at the same polymerase active site used for chain elongation, it must occur through the opposite side of the nucleotide channel used for chain elongation. How the uridylated VPg is transferred to the front side of the polymerase for use in priming RNA synthesis is not known. The primer might be transferred through the nucleotide channel, or, as suggested by experimental results, to another polymerase molecule.⁴⁸⁵ Resolution of the structure of rhinovirus 3D^{pol} suggested that VPg could bind via the front face of the polymerase.²² However, structure of the FMDV 3D^{pol} bound to VPg revealed that the protein does not bind to the active site, consistent with the results of genetic analyses. Whether there are virus-specific mechanisms of VPg priming remains to be determined.

Cellular Site of RNA Synthesis

Picornaviral RNA synthesis, like that of most RNA viruses, occurs in the cytoplasm of the cell. Picornavirus infection leads to the proliferation and rearrangement of intracellular membranes in infected cells. The ER and Golgi apparatus are destroyed in this process, and the cytoplasm fills with double-membraned vesicles.^{115,447} Viral RNA replication occurs on the cytoplasmic surfaces of these vesicles.^{63,92,133} Membrane localization of viral RNA replication proteins may ensure high local concentrations of replication components, increasing the rates or efficiencies of replication reactions. It has also been suggested that membrane localization of viral RNA replication proteins could promote their oligomerization.³¹¹

Poliovirus proteins 3A and 2BC are sufficient to induce the formation of vesicles that are biochemically and ultrastructurally similar to those observed in virus-infected cells.⁴⁷⁶ Because viral proteins 2A and 2BC are known to localize to the ER, a plausible hypothesis is that they promote vesicle formation from this site.¹²⁴ One source of virus-induced vesicles may be those that participate in ER-to-Golgi trafficking. Budding of vesicles from the ER is initiated by COPII coats; these fuse to create the ER-Golgi intermediate compartment (ERGIC). COPI coats initiate budding of vesicles from the ERGIC that move to the Golgi. It has been suggested that poliovirus-induced vesicles are morphologically similar to COPII vesicles, which are involved in anterograde transport.⁴⁴² The COPII proteins Sec13/31 were shown to colocalize with the viral 2B protein on the surface of the vesicles. The inhibition of poliovirus and rhinovirus RNA replication by brefeldin A, however, apparently contradicts this hypothesis.^{158,233,324} Brefeldin A interferes with formation of COPI, but not COPII or autophagic vesicles, by inhibiting the exchange of guanosine triphosphate (GDP) for guanosine triphosphate (GTP) by the adenosine diphosphate (ADP) ribosylation factor, Arf. Brefeldin prevents COPI coat assembly by targeting the Arf1 guanine exchange factors

GBF1, BIG1 and BIG2. A brefeldin-resistant form of GBF1 was found to allow poliovirus replication in the presence of the drug.⁵⁴ Viral protein 3A binds GBF1, recruiting it to replication complexes, and this interaction, which BFA functionally interferes with, is required for replication.^{54,290} When poliovirus proteins are synthesized in cells in the absence of viral RNA replication, membrane remodeling is insensitive to brefeldin A, indicating that the drug inhibits viral replication (by interfering with GBF1), not remodeling of cellular membranes.⁵⁴

The binding of 3A to GBF1 diverts the protein from its normal function in the secretory pathway, and explains inhibition of protein secretion by viral infection.¹²³ The result is an inhibition of COPI vesicle formation; these may be diverted to form viral replication complexes. In support of this hypothesis, components of COPI coats have been found in association with echovirus replication complexes.¹⁵⁸

The vesicles induced during poliovirus and rhinovirus infection may also be derived from the cellular autophagosomal pathway. In response to a variety of stimuli, including cellular starvation, cells break down cytoplasmic proteins and organelles within autophagosomes, double-membraned structures that mature and become degradative. The poliovirus-induced vesicles bear several hallmarks of autophagosomes, including their double-membraned structure, the presence of cytoplasmic content within the vesicles,⁴⁴⁷ and colocalization with autophagosomal markers latency-associated membrane protein 1 (LAMP1) and LC3.²³⁹ In support of the autophagosomal origin of virus-induced vesicles, stimulation of autophagy increased virus yield, whereas inhibition of the autophagosomal pathway by drugs or small interfering RNA (siRNA) reduced virus yield.²³⁹ These findings indicate that components of the cellular autophagosomal pathway are subverted to provide membranous supports for viral RNA replication complexes. Autophagosomes are induced during infection with other picornaviruses, including FMDV, enterovirus 71, EMCV, rhinoviruses, and coxsackieviruses (reviewed in²⁷⁷). They are not present in rhinovirus 1A-infected cells,⁴¹⁴ however, and it is not clear if they are needed for replication of rhinovirus 2.⁷⁵ Replication membranes in rhinovirus 1A-infected cells appear to be derived from the Golgi apparatus, whose fragmentation correlates with the presence of the viral 3A protein.⁴¹⁴

A recent study on the three-dimensional architecture of the poliovirus-induced replication complexes revealed that membrane remodeling begins with the formation, often in association with a Golgi antigen, of a network of irregularly shaped, single-membrane, branching tubular structures.⁵⁵ Later in infection these become double-membraned structures, but the highest rates of viral RNA synthesis occur when the mainly single-membraned convoluted tubules are present.

At least two viral proteins, 2C and 3AB, bring the replication complex to membranous vesicles. As discussed, 3AB is a hydrophobic protein that anchors the protein primer VPg in the membrane for RNA synthesis. Protein 3AB binds 3D^{pol} and 3CD^{pro}, thereby recruiting the replication complex to membranes. Protein 2C has an RNA-binding domain, which could also anchor viral RNA to membranes in the replication complexes.¹³²

Translation and Replication of the Same RNA Molecule

The genomic RNA of picornaviruses is not only mRNA but also the template for synthesis of negative-stranded RNA. How

does the viral polymerase, traveling in a 3' to 5' direction on the positive strand, avoid collisions with ribosomes translating in the opposite direction? It is believed that a mechanism exists to avoid the two processes occurring simultaneously. *In vitro* experiments using inhibitors of protein synthesis demonstrate that, when ribosomes are frozen on the viral RNA, replication of the RNA is inhibited. In contrast, when ribosomes are released from the viral RNA, its replication is increased.³⁹ These results suggest that replication and translation cannot occur on the same template simultaneously.

A mechanism for regulating viral RNA translation and replication involves cleavage of poly r(C)-binding protein. This protein functions in IRES-dependent translation by binding stem-loop IV^{65,155} (Fig. 16.15), and in viral RNA synthesis by binding stem-loop I.^{157,377} Poly r(C)-binding protein is cleaved by viral 3C^{pro}; the cleaved protein can no longer stimulate IRES-dependent protein synthesis but is competent to participate in the initiation of viral RNA synthesis.³⁸⁶ Another mechanism involves binding of 3CD to stem-loop I, which increases the binding affinity of poly r(C)-binding protein for stem-loop I and decreases it for stem-loop IV.¹⁵⁶ Cleavage of PTB by 3C^{pro} also leads to reduced viral translation.²⁶ The consequence of these modifications is that viral IRES-dependent translation is down-regulated, and ribosomes are cleared from the viral mRNA, allowing unimpeded transit of RNA polymerase.

Whether there exist mechanisms to regulate translation and replication of RNA, experimental evidence indicates that some ribosome and RNA polymerase collisions do occur. This conclusion is based on the isolation of a poliovirus variant whose genome contains an insertion of a 15 nucleotide sequence from 28S ribosomal RNA (rRNA).⁸⁸ Apparently, the RNA polymerase collided with a ribosome, copied 15 nucleotides of rRNA, and then returned to the viral RNA template.

Discrimination of Viral and Cellular RNA

The RNA-dependent RNA polymerases of picornaviruses are template-specific enzymes. Poliovirus 3D^{pol} copies only viral RNA, not cellular mRNA, in infected cells. The purified enzyme, however, will copy any polyadenylated RNA if provided with an oligo(U) primer. This observation has led to the suggestion that template specificity probably resides in the interaction of replication proteins with sequence elements in the viral RNA. The *cis*-acting RNA elements located within the coding region of picornaviruses, which direct the uridylylation of VPg, are binding sites for 3CD^{pro} (Fig. 16.13). The 3'-noncoding region of the viral positive-stranded RNA contains an RNA pseudoknot conserved among picornaviruses that is believed to play a role in the specificity of copying by 3D^{pol}.²⁴¹ Disruption of the pseudoknot by mutagenesis produces viruses that have impaired RNA synthesis, indicating the importance of the structure in the synthesis of negative-stranded RNA. 3D^{pol} or 3CD^{pro} cannot bind to the 3' end of poliovirus RNA unless 3AB is present. The interaction of 3AB-3D^{pol} may determine the specificity of binding to the 3' pseudoknot.

Despite experimental results that underscore the importance of the pseudoknot in RNA synthesis, polioviruses from which the entire 3'-noncoding region of the viral RNA has been removed are able to replicate.^{77,489} This finding has led to the suggestion that template specificity imparted by termi-

FIGURE 16.15. Morphogenesis of picornaviruses. The capsid protein precursor, P1, folds nascently, is cleaved from P2, and then is further cleaved to VP0 + VP3 + VP1 by 3CD^{pro}. Protomers (5S) self-assemble into 14S pentamers, and pentamers assemble into 80S empty capsids. In one model of encapsidation, RNA is threaded into the empty capsid, producing a 150S provirion in which VP0 is uncleaved. Another possibility is that pentamers assemble around the RNA genome and that empty capsids are storage depots for pentamers. Cleavage of VP0 is the final morphogenetic step that produces the infectious 160S virion. The proteinase responsible for the cleavage of VP0 is unknown.

nal structures of RNA might be of greater importance early in infection. During the initiation phases of replication, the 3' pseudoknot structure might facilitate template selection when few viral polymerase molecules are available and membrane association has not yet provided high concentrations of replication components. Later, determinants of template selection by the polymerase might include the membrane association of the RNA polymerase. Template specificity may also be conferred

by the position of the 3D^{pol} gene at the very 3' end of the viral RNA; translation places the polymerase at the 3' end of the genome, ready for initiation.

A cloverleaf-like structure that forms in the 5'-noncoding region also plays an important role in template specificity. The finding that a mutation in a cloverleaf-like structure in the 5'-noncoding region that affects RNA synthesis could be complemented by a suppressor mutation in 3C^{pro} led to the suggestion that 3C^{pro} might bind the cloverleaf and play a role in viral RNA replication.¹⁷ It was subsequently found that 3CD^{pro} binds the cloverleaf structure in the positive strand, together with a cellular protein, now known to be poly r(C)-binding protein, that is required for complex formation.^{16,18,377} The RNA-binding domain of 3CD^{pro} is contained within the 3C^{pro} portion of the protein, on the opposite face of the molecule from the site involved in proteolysis. Mutations within this domain abolish complex formation and RNA replication without affecting viral protein processing. 3CD^{pro}, therefore, plays an important role in viral RNA synthesis by participating in formation of a ribonucleoprotein complex at the 5' end of the positive-stranded RNA. A structural model of rhinovirus 3C^{pro} bound to stem-loop I shows that RNA binding induces changes in the proteinase active site, although their effect on catalytic activity is not known.⁹⁴ A role for these interactions in viral RNA replication is suggested in the model in Figure 16.13.

ORIGINS OF DIVERSITY

Misincorporation of Nucleotides

As with all other RNA viruses, the picornaviruses have very high error rates, because of misincorporation during chain elongation and the lack of proofreading ability in RNA polymerases. With error frequencies as high as one misincorporation per 10³ to 10⁴ nucleotides, RNA virus populations exist as *quasispecies*, or mixtures of many different genome sequences.¹²⁵

It has been suggested that RNA viruses exist on the threshold of error catastrophe, to maximize diversity and adaptability.¹²⁵ A moderate increase in error frequency would be expected to destroy the virus population. In one study, it was estimated that each poliovirus genome synthesized after multiple rounds of replication in an infected cell contains two point mutations.¹¹¹ In the presence of the antiviral drug ribavirin, each poliovirus genome contained 15 point mutations, and yields of poliovirus in infected cells were 0.00001% of untreated cells. Similar observations have been made with FMDV¹⁸⁸ and Coxsackievirus B3.¹⁷⁹ These findings demonstrate that RNA viruses do exist at the error threshold, and that ribavirin is an RNA virus mutagen that inhibits virus replication by increasing the RNA polymerase error rate beyond the threshold.

High RNA virus error rates are believed to be necessary to enable survival of the virus population under selective pressure. Consequently, viruses with less error-prone RNA polymerases should be at a competitive disadvantage in complex environments such as an infected animal. To test this hypothesis, a poliovirus mutant resistant to the antiviral effects of ribavirin was isolated.^{393,513} Resistance to ribavirin was conferred by a single amino acid change in 3D^{pol} that reduces errors during replication. The high-fidelity mutant virus replicated and spread

poorly in mice, and was unable to compete with a low-fidelity virus. The results indicate that mutations, and the formation of a diverse quasispecies, benefits viral populations, particularly in an infected animal. Analysis of a ribavirin-resistant mutant of FMDV reveals no restriction of the viral quasispecies.²³ This apparent paradox is explained by the observation that the RNA polymerase mutation increased the frequency of misincorporation of natural nucleotides while decreasing the frequency of the incorporation of ribavirin nucleotide.

Recombination

Recombination, the exchange of nucleotide sequences among different genome RNA molecules, was first discovered in cells infected with poliovirus, and was subsequently found to occur during infection with other positive- and negative-stranded RNA viruses. The frequency of recombination, which is calculated by dividing the yield of recombinant virus by the sum of the yields of parental viruses, can be relatively high. In one study of poliovirus and FMDV, the recombination frequency was 0.9%, leading to the estimation that 10% to 20% of the viral genomes recombine in one growth cycle. When poliovirus recombination is studied by quantitative polymerase chain reaction, obviating the necessity to select for viable viruses, the recombination frequency for marker loci 600 nucleotides apart is 2×10^{-3} , similar to estimates obtained using selectable markers.²⁴⁴ RNA recombination also occurs in natural infections. For example, intertypic recombinants among the three serotypes of Sabin poliovirus vaccine strains are readily isolated from the intestines of vaccinees; some recombinants contain sequences from all three serotypes.⁸⁰ The significance of these recombinants is unknown, but it has been suggested that such viruses are selected for their improved ability to replicate in the human alimentary tract compared with the parental viruses. Recombination in nature has also been demonstrated among nonpolio enteroviruses⁴⁶⁰ (reviewed in³⁰⁹).

Poliovirus recombination, which mainly occurs between nucleotide sequences of the two parental genome RNA strands that have a high percentage of nucleotide identity, is called *base pairing dependent* (Fig. 16.14). RNA recombination is believed to be coupled with the process of genome RNA replication: it occurs by template switching during negative-strand synthesis, as first demonstrated in poliovirus-infected cells²⁷⁵ and subsequently in cell-free extracts.⁴⁸² The RNA polymerase first copies the 3' end of one parental positive strand, then switches templates and continues synthesis at the corresponding position on a second parental positive strand. Template switching in poliovirus-infected cells occurs predominantly during negative-strand synthesis because the concentration of positive-strand acceptors for template switching is 30 to 70 times higher than that of negative-strand acceptors. This template-switching mechanism of recombination is also known as *copy-choice*. A prediction of the copy-choice mechanism is that recombination frequencies should be lower between different poliovirus serotypes, a prediction that has been verified experimentally. For example, recombination between poliovirus types 1 and 2 occurs about 100 times less frequently than among type 1 polioviruses (the different poliovirus serotypes differ by about 15% in their nucleotide sequences).²⁷³ The cause of template switching is not known, but it might be triggered by pausing of the polymerase during chain elongation.

ASSEMBLY OF VIRUS PARTICLES

Morphogenesis of picornaviruses has been studied extensively because the 60-subunit capsid is relatively simple and the assembly intermediates can be readily detected in infected cells (Fig. 16.15). During the synthesis of the P1 protein, the capsid protein precursor, the central β -barrel domains form, and intramolecular interactions among the surfaces of these domains lead to formation of the structural units. Once P1 is released from the 2A protein, the VP0–VP3 and VP3–VP1 bonds are cleaved by proteinase 3CD^{pro}. These cleavage sites are located in flexible regions between the β -barrels; considerable movement of the aminotermini and carboxyltermini occurs after cleavage, but the contacts between β -barrels are not disturbed.²²³ In the mature capsid, the carboxyltermini of VP1, VP2, and VP3 are on the outer surface of the capsid, whereas the aminotermini are on the interior, where they participate in an extensive network of interactions among protomers. This process produces the first assembly intermediate in the poliovirus pathway, the 5S protomer, the immature structural unit consisting of one copy each of VP0, VP3, and VP1. Five protomers then assemble to form a pentamer, which sediments at 14S. Cleavage of P1 is probably required for assembly of the pentamer.³⁷³ This conclusion is supported by examination of the virion structure. The β -cylinder at the fivefold axis of symmetry is formed from the N-termini of neighboring VP3 molecules; the cylinder is surrounded by a bundle composed of the aminotermini of VP0 and VP1. For these interactions to occur, proteolytic cleavage of the capsid proteins must occur to allow movement of the aminotermini.

Pentamers are important intermediates in the assembly of all picornaviruses.^{67,433} They can self-assemble *in vitro* or *in vivo* into 80S empty capsids; in one model of assembly, newly synthesized viral RNA is inserted into these particles to form the provirion,²⁴⁰ in which the capsid protein VP0 remains uncleaved. This assembly model would seemingly require an opening in the empty capsid through which the RNA can enter. Examination of the high-resolution x-ray crystallographic structure of these particles does not provide evidence for such an opening.⁴¹ This finding does not exclude this morphogenetic pathway because the pore might be dynamic and not observed in the crystals. In an alternative morphogenesis pathway, 4S pentamers assemble with virion RNA to form provirions. In this model, for which there is some experimental support,³⁶⁵ the empty capsids found in infected cells serve as storage depots for 14S pentamers.

The final morphogenetic step involves cleavage of most of the VP0 molecules to VP4 + VP2. The proteinase that carries out this final maturation cleavage has not been identified. The VP0 scissile bond is located on the interior of empty capsids and mature virions and is inaccessible to viral or cellular proteinases. The presence of a conserved serine in VP2 near one of the cleaved termini of VP2 led to a model that cleavage occurs by a novel autocatalytic serine protease-like mechanism in which basic viral RNA groups serve as proton abstracters during the cleavage reaction.²⁴ Replacement of ser-10, however, does not impair VP0 cleavage.²⁰⁵ In another hypothesis, a conserved histidine in VP2 is involved in catalysis, together with the viral RNA.^{41,114} Replacement of this histidine with different amino acids leads to lack of infectivity or highly unstable

particles, supporting the involvement of VP2 histidine 195 in mediating VP0 cleavage during assembly.²¹⁶

The structure of the 80S particle reveals differences in the network formed by the N-terminal extensions of the capsid proteins on the inner surface of the shell, compared with the native virion.⁴¹ In empty capsids, VP4 and the entire N-terminal extensions of VP1 and VP2 are disordered, and many stabilizing interactions that are present in the mature virion are not present. Thus, cleavage of VP0 establishes the ordered N-terminal network, an interlocking seven-stranded β -sheet formed by residues from adjacent pentamers. This network results in an increase in particle stability and the acquisition of infectivity.

The picornavirus encapsidation process is highly specific, resulting in packaging of only positive-stranded RNA, and not viral mRNA, negative-stranded viral RNA, or any cellular RNA.^{363,364} VPg is probably not an encapsidation signal because VPg-containing negative-stranded RNA is not packaged. The coupling of encapsidation to viral RNA synthesis may explain the selective packaging of viral positive-stranded RNA. In infected cells, newly synthesized RNA is packaged into virions within 5 minutes, whereas incorporation of capsid proteins in virions requires at least 20 minutes.³¹ The pool of viral RNA available for packaging, therefore, is small, and the pool of capsid proteins is large. If capsid formation is inhibited with *p*-fluorophenylalanine, the accumulated RNA cannot be packaged after removal of the inhibitor.¹⁹⁹ These results suggest that packaging of the viral genome is linked to RNA synthesis, and would explain why only RNA containing VPg are encapsidated. This conclusion is questioned by more recent findings showing that inhibition of virion assembly by hydantoin, which targets the 2C protein, does not effect genome replication. Furthermore, when hydantoin from infected cells after RNA synthesis is complete, and in the presence of an inhibitor of replication, normal levels of virions are produced.³⁶⁹

During its synthesis, the P1 capsid protein precursor is linked to myristic acid at the aminoterminal glycine residue of VP4 that is exposed after removal of the initiation Met residue.⁹³ The myristate groups, which form part of a network of interactions between subunits that form when protomers assemble into pentamers, cluster around the fivefold axis of symmetry and stabilize the β -cylinder that is made by the aminotermini of five copies of VP3. Mutagenesis indicates that the myristate group plays a role in stabilizing pentamers and, therefore, virions.^{20,314–316,344}

EFFECTS OF VIRAL MULTIPLICATION ON THE HOST CELL

Inhibition of 5' End–Dependent mRNA Translation Cleavage of eIF4G

In cultured mammalian cells, poliovirus infection results in inhibition of cellular protein synthesis. By 2 hours after infection, polyribosomes are disrupted and translation of nearly all cellular mRNA stops, replaced by viral mRNA translation (Fig. 16.16). Poliovirus mRNA, but not capped mRNA, can be translated in extracts from infected cells. In such extracts, the eIF4GI/II component of the translation initiation factor eIF4F has been cleaved.^{136,434,496} Cleavage of eIF4G separates the N-terminal eIF4E-binding domain of eIF4G from the C-terminal fragment

FIGURE 16.16. Inhibition of cellular translation in cells infected with poliovirus. **A:** Protein synthesis in poliovirus-infected and uninfected cells at different times after infection. Poliovirus infection results in inhibition of host cell translation beginning about 1 hour after infection. The increase in translation beginning 3 hours after infection is caused by the synthesis of viral proteins. **B:** Polyacrylamide gel showing inhibition of cellular translation. At different times after infection (top of each lane), cells were incubated with ^{35}S -methionine for 15 minutes; the cell extracts were then fractionated on an SDS-polyacrylamide gel. By 5 hours after infection, host translation is markedly inhibited and replaced by the synthesis of viral proteins, identified at the right.

(Fig. 16.17). The assumption that the C-terminal fragment of eIF4G cannot support the translation of capped mRNA has been proved incorrect.¹⁰ It is now believed that picornavirus-induced translational inhibition is not caused by inability of p100 to support capped mRNA translation, but to the viral RNA outcompeting host cell mRNA for the limiting concentration of p100. Optimal function of the IRES does require the C-terminal frag-

ment of eIF4G, which, as discussed previously, is necessary to anchor 40S ribosomal subunits to the IRES. Although both eIF4GI and eIF4GII are cleaved in poliovirus- and rhinovirus-infected cells, the kinetics of shutoff of host translation correlates with cleavage of eIF4GII and not eIF4GI.^{180,478}

Both forms of eIF4G are cleaved by protease 2A^{pro} of poliovirus and rhinovirus.^{180,478} *In vitro* cleavage of eIF4G by purified 2A^{pro} of rhinovirus is inefficient unless eIF4G is bound to eIF4E.¹⁹⁷ This finding indicates that eIF4G is not cleaved as an individual polypeptide, but rather as part of the eIF4F complex. Binding of eIF4E to eIF4G may induce conformational changes in eIF4G that make it a more efficient substrate for the protease. Poliovirus 2A^{pro} efficiently cleaves eIF4GI, but not eIF4GII, consistent with the differential cleavage of these proteins during virus infection.¹⁸⁰ The L^{pro} protein cleaves eIF4GI in cells infected with FMDV. The cleavage sites in eIF4GI for the two proteinases are different: L^{pro} cleaves between Gly-479 and Arg-480, whereas 2A^{pro} cleaves between Arg-486, and Gly-487.^{274,288}

Modulation of eIF4F Activity

Two related low-molecular-weight cell proteins, 4E-BP1 and 4E-BP2, bind to eIF4E and inhibit translation by 5' end-dependent scanning, but not by internal ribosome entry (Fig. 16.17).³⁸³ 4E-BP1 is identical to a protein called PHAS-I (phosphorylated heat- and acid-stable protein regulated by insulin), which was previously known to be an important phosphorylation substrate in cells treated with insulin and growth factors.³⁰¹ Phosphorylation of 4E-BP1 *in vitro* blocks its association with eIF4E. Binding of either 4E-BP1 or 4E-BP2 to eIF4E does not prevent it from interacting with the 5' cap but does inhibit binding to eIF4G. Consequently, active eIF4F is not formed. eIF4G and the 4E-BP have a common sequence motif that binds eIF4E. Treatment of cells with hormones and growth factors leads to the phosphorylation of 4E-BP1 and its release from eIF4E. Those mRNAs with extensive secondary structure in the 5'-untranslated region, which are translated poorly, are preferentially sensitive to the phosphorylation state of 4E-BP1. As expected, translation by internal ribosome binding is not affected when 4E-BP1 is dephosphorylated. Binding of extracellular ligands leads to phosphorylation of 4E-BP through a signaling pathway that includes the target of rapamycin.⁵³²

Infection with several picornaviruses causes alteration of the phosphorylation state of 4E-BP1 and 4E-BP2 (Fig. 16.17). Infection of cells with encephalomyocarditis virus causes inhibition of cellular translation, but in contrast to the shutoff that occurs in poliovirus-infected cells, shutoff of cellular protein synthesis occurs late in infection and is not mediated by cleavage of eIF4G. Infection with encephalomyocarditis virus induces dephosphorylation of 4E-BP1, which then binds eIF4E to prevent it from forming eIF4F.¹³² Translation of cellular mRNA is inhibited, but that of the viral RNA is not inhibited because it contains an IRES. Dephosphorylation of 4E-BP1 also occurs late in cells infected with poliovirus, but this event does not coincide with inhibition of cellular translation, which occurs earlier in infection.¹⁶⁵ Inhibition of translation by dephosphorylation of 4E-BP also influences the ability of the cell to productively combat viral infection by reducing production of type I interferons.⁹⁷

Efficient translation initiation requires the formation of a closed loop on mRNA. Circularization of the RNA is mediated

FIGURE 16.17. Two mechanisms for regulating eIF4F activity in picornavirus-infected cells. The proteins 4E-BP1 and 4E-BP1 bind eIF4E and prevent it from interacting with eIF4G. 4E-BP1 binds eIF4E when it is dephosphorylated, an event that occurs in cells infected with poliovirus and encephalomyocarditis virus. Cleavage of eIF4G takes place in cells infected with poliovirus, rhinovirus, and foot-and-mouth disease virus, among others. Cleavage reduces the efficiency of translation of capped messenger RNA (mRNA). 5' end-dependent initiation is inhibited because capped mRNA cannot compete with viral mRNA for the translation machinery.

by the interaction of eIF4G bound at the 5' end of the RNA and poly(A) binding protein bound to the poly(A) tail at the 3' end. The initial synthesis of picornavirus specific proteins is stimulated by the interaction of eIF4G with poly(A) binding protein.^{333,479} Like eIF4G, poly(A) binding protein is cleaved during enterovirus infection by viral proteinases 2A^{pro} and 3C^{pro}; however, the kinetics of poly(A) binding protein cleavage are slower than those of eIF4G.²⁴⁷ Cleavage of poly(A) binding protein is necessary but not sufficient for efficient inhibition of cellular translation; instead, cleavage of this protein is believed to participate in the switch from RNA translation to replication (see “Translation and Replication of the Same RNA molecule”).⁶⁸ The effect of poly(A) binding protein cleavage during this switch is controversial, as depletion of poly(A) binding protein from cell lysates did not reduce virus production.⁴⁸⁰ The cellular polyadenylation factor CstF-64 is cleaved by enterovirus 71 3C^{pro} proteinase, impairing the addition of poly(A) to host cell mRNAs.⁵²⁴

Formation of the eIF4F complex can also be regulated by miRNAs. During enterovirus infection, transcription of miR-141 is enhanced. Because multiple binding sites for this miRNA are found within the 3'-UTR of the eIF4E mRNA, levels of eIF4E—and consequently the eIF4F complex—are reduced, and cellular protein synthesis is impaired.²¹⁹ Viral translation is unaffected as it does not require eIF4E.

The production of double-stranded RNA during infection with many viruses leads to activation of Pkr, phosphorylation of eIF2 α , and inhibition of translation. It occurs very late in the replication cycle of poliovirus.³⁶⁸ Like most cellular mRNAs, the polyprotein encoded by picornaviral mRNA begins with an AUG, and early in infection initiation of protein synthesis requires the ternary complex of eIF2-GTP-met-tRNA_i. Late in infection, phosphorylation of serine 52 of the alpha subunit of eIF2 prevents the recycling of the ternary complex after initiation. However, poliovirus specific protein synthesis continues

throughout infection. It is believed that initiation of translation late during infection occurs independently of eIF2.^{523,530} The exact mechanism for this mode of initiation is not well understood but is thought to be dependent on the generation of a fragment of eIF5 that functions in a similar manner as eIF2 in recruiting the initiating tRNA to the small 40S ribosomal subunit while bound to the mRNA.⁵³⁰ The proteolytic activity of 2A^{pro} is believed to be required to enable poliovirus mRNA translation in the absence of eIF2.⁴¹⁹

Stress-Associated RNA Granules

Sequestering of mRNA away from the translation apparatus in processing (P) bodies and stress granules is another mechanism by which cellular mRNA translation can be impaired.¹⁵ P bodies and stress granules are two nonmembranous cytoplasmic aggregates composed of RNA and protein, including many proteins involved in mRNA translation. These granules are believed to form when translation is inhibited in the presence of intracellular and extracellular stresses, including viral infection. When stress conditions are alleviated, the mRNAs found in these aggregates can either be deadenylated and degraded or returned to the pool of actively translated RNAs.

Stress granules are thought to be nucleated on two cellular proteins, T-cell-restricted intracellular antigen-1 (TIA-1) and the RasGAP SH3-domain binding protein 1 (G3BP). Reduction of either protein impairs formation of stress granules, and overproduction of either component stimulates formation of these aggregates.^{164,494} Stalled translation complexes consisting of mRNA, eIF4E, eIF4G, eIF4A, eIF3, poly(A) binding protein, and phosphorylated eIF2 α are found within these granules. The presence of phosphorylated eIF2 α is a hallmark of stress granules. Formation of stress granules is enhanced during early picornavirus infection, and correlates with the inhibition of cellular translation but is independent of eIF2 α phosphorylation. Late in viral infection, the viral proteinase 3C^{pro} cleaves

RasGAP SH3-domain binding protein 1la, disassembling stress granules, an event required for efficient viral replication. The presence of an altered form of cleaved RasGAP SH3-domain binding protein 1^{Q326E} prevents the disassembly of stress granules and impairs viral replication.⁵²⁸ Instead, a noncanonical form of stress granules remains, an aggregate containing only TIA-1.^{400,529} The opposite is observed during infection with members of the *Discitroviridae*: cricket paralysis virus infection prohibits stress granule formation as defined by foci of the *Drosophila* homologs of TIA-1 and RasGAP SH3-domain binding protein 1, Rcx8 and Rin. Addition of potent inducers of stress granules such as arsenite and patemine A to the culture medium is unable to overcome viral inhibition.²⁶⁹

Processing (P-) bodies are a second type of nonmembrane bound aggregate found in the cytoplasm. These aggregates, which are the sites of RNA deadenylation and mRNA repression, are composed of proteins such as the decapping enzymes Dcp1a, Dcp2, and proteins that mediate mRNA deadenylation including Pan3, the CCR4/Not 1 complex, Xrn-1, a 5'-3' RNA exonuclease, and the DEAD-box helicase p54/Rck. In uninfected cells, P-bodies are the consequence of micro RNA (miRNA)-mediated repression.¹³⁷ Ultrastructural analysis of these granules suggests that there is an anchoring core composed of proteins required for repression with proteins mediating decay on the periphery. The protein that bridges between the two regions of the aggregate is p54/Rck.¹⁰³ P-bodies are found in proximity to both the ribosome and mitochondria. Although cellular mRNA translation is inhibited during picornavirus infection, the RNA is not degraded, possibly due to inhibition of P-body formation. The 3C^{pro} proteinase of poliovirus cleaves several P-body components including Xrn1, Dcp1a, and Pan 3, disrupting P-body formation.¹²⁸

Inhibition of Cellular RNA Synthesis

Infection of cells with picornaviruses leads to a rapid inhibition of host cell RNA synthesis catalyzed by all three classes of DNA-dependent RNA polymerase. RNA polymerases I, II, and III from poliovirus-infected cells are enzymatically active, suggesting that accessory proteins may be the target of transcriptional inhibition. Studies of *in vitro* systems have demonstrated the inhibition of specific transcription factors required by each of the three RNA polymerases. The RNA polymerase factor TFIID, which is a multiprotein complex, is inactivated in poliovirus-infected cells.²⁷⁹ This inactivation appears to be caused, at least in part, by cleavage of a subunit of TFIID, the TATA-binding protein, by protease 3C^{pro}.⁷⁹ A pol III DNA-binding transcription factor, TFIIC, is also cleaved and inactivated by 3C^{pro}.⁹⁶ The target of 3C^{pro} is a subunit of TFIIC, which contacts the pol III promoter. The pol I transcription factors SL-1 (selectivity factor) and UBF (upstream binding factor) are inactivated in poliovirus-infected cells by 3C^{pro}, resulting in inhibition of pol I transcription.^{32,439}

Because poliovirus replication occurs in the cytoplasm, cleavage of RNA polymerase transcription factors requires that the viral proteinase 3C^{pro} enter the nucleus. 3C^{pro} lacks a nuclear localization signal (NLS), but the precursor 3CD^{pro} enters the nucleus by virtue of an NLS in protein 3D^{pol}. Transcription factors in the nucleus are then cleaved by either 3CD^{pro} or 3C^{pro} that is released by autocatalysis.⁴⁵⁵ Rhinovirus 16 3CD^{pro} has also been shown to enter the nucleus.¹⁴

Inhibition of Nucleocytoplasmic Trafficking

Infection of cells with picornaviruses leads to the disruption of nucleocytoplasmic trafficking. One mechanism by which this is achieved is the proteolysis of nucleoporins, proteins that constitute the nuclear pore complex. In cells infected with poliovirus, two protein components of the nuclear pore complex are cleaved, Nup153 and Nup62.^{191,192} The proteinase responsible for cleavage of Nup62 in rhinovirus-infected cells is 2A^{pro}.³⁷⁶ This cleavage results in the cytoplasmic accumulation of nuclear proteins, some of which, such as La protein⁴⁵⁹ and SRp20,¹⁴⁰ are required for viral replication. The rates and processing profiles of Nup by 2A^{pro} proteinases of different rhinoviruses vary widely.⁵²² The rhinovirus 3C^{pro} and its precursor 3CD^{pro} are imported into the nucleus, leading to the degradation of nuclear pore components.¹⁶⁰

Another mechanism of disruption of nucleocytoplasmic trafficking involves the L protein of cardioviruses (the 2A protein of these viruses is not a proteinase). The L protein binds directly to the Ran-GTPase, a key regulator of nucleocytoplasmic transport.⁴⁰⁶ Infection also leads to phosphorylation of nucleoporins Nup62, Nup153, and Nup214.⁴⁰⁷ Staurosporine, a broad-spectrum protein kinase inhibitor, and ERK and p38 MAP kinase inhibitors block Nup phosphorylation and restore normal nuclear trafficking.⁴⁰⁸ Inhibition of Nup activity is therefore achieved by phosphorylation in cardiovirus-infected cells and by proteolysis in cells infected with enteroviruses.

The disruption of nucleocytoplasmic trafficking by picornaviruses not only provides cytoplasmic access to nuclear proteins needed for viral replication, but blocks the export of cell mRNAs with antiviral activity produced as part of the innate immune response.

Inhibition of Protein Secretion

Transport of both secretory and plasma membrane proteins is blocked in picornavirus-infected cells.¹²³ The 2B and 2BC proteins block protein secretion from the Golgi apparatus, and the 3A protein blocks vesicular traffic from the ERGIC to the Golgi complex.^{34,62,124,444} Inhibition of protein secretion by poliovirus protein 3A is not required for viral growth in cell culture.¹²² Protein 3A inhibits protein transport by binding to and inhibiting GBF1, a guanine exchange factor that is needed for activity of Arf1 and is required for the transport through the secretory pathway.⁵⁴ Cells infected with the poliovirus mutant 3A-2, which has a single amino acid change in the protein, have reduced inhibition of protein transport.¹²⁴ This amino acid change abrogates binding of 3A to GBF1 and therefore does not inhibit activity of the protein.^{525,527} Because the 3A protein prevents secretion of cytokines¹²² and major histocompatibility complex I (MHC-I)-dependent antigen presentation,¹¹⁷ it is likely to modulate the innate and adaptive immune responses of the host and, therefore, the outcome of infection. Consistent with this hypothesis, when the 3A mutation is introduced into the genome of Coxsackievirus B3, the mutant is less pathogenic in mice, although the mechanism of attenuation is not known.⁵²⁶ Inhibition of protein secretion in cells infected by FMDV is caused not by protein 3A but by protein 2BC.³³⁷

Cell Death and Virus Release

When cells are productively infected with poliovirus, they develop the characteristic morphologic changes known as

cytopathic effects. These include condensation of chromatin, nuclear blebbing, proliferation of membranous vesicles, changes in membrane permeability, leakage of intracellular components, and shriveling of the entire cell. The cause of cytopathic effects is unknown. One hypothesis is that leakage of lysosomal contents is partly responsible.¹⁹⁰ Although cellular RNA, protein, and DNA synthesis are inhibited during the first few hours of infection, they cannot account for cytopathic effects.

When poliovirus reproduction is hindered by certain drugs or other restrictive conditions, cell death occurs through induction of apoptosis.⁴⁹⁰ Although certain manifestations of cytopathic effects and apoptosis are similar (e.g., chromatin condensation and nuclear deformation), the pathways leading to their induction differ.³ During productive infections of cultured cells with poliovirus, apoptosis is blocked by a virus-encoded inhibitor.⁴⁹⁰ Viral replication and central nervous system injury in mice infected with poliovirus, however, are associated with apoptosis.¹⁶⁷ Viral inducers of apoptosis include proteins 2C, 2A^{pro}, and 3C^{pro},^{36,168,303} and inhibitors of apoptosis include L^{pro}, 2B, and 3A.^{82,122,159,355,538} The ability of different strains of Theiler's murine encephalomyelitis virus to induce apoptosis may be a determinant of disease. The TO strain of Theiler's virus, which causes a persistent demyelinating disease in mice, encodes an additional protein, L*.⁹⁰ This protein is produced by initiation from an AUG that is 13 nucleotides downstream from the initiator AUG of the polyprotein, in a different reading frame. In contrast, nondemyelinating strains of the virus (e.g., GDVII) do not encode L*. It was subsequently found that L* has antiapoptotic properties in macrophages, is critical for virus persistence,¹⁵⁹ and prevents antiviral cytotoxic T-cell activation.⁵³⁸ The ability of L* to inhibit apoptosis may be a key factor in determining whether infection of mice results in acute disease or persistence and demyelination.

The autophagosomes that form in cells infected with some picornaviruses (see "Cellular Site of Viral RNA Synthesis") may also play a role in virus release from the cell. Suppressing proteins in the autophagic pathway reduces viral release, suggesting a mechanism for nonlytic exit of newly synthesized virus from the infected cell.⁴⁸⁴

PERSPECTIVES

Since the identification in 1908 of poliovirus as the etiologic agent of poliomyelitis, research on the virus has waxed and waned. With each lull in activity, questions were raised about whether it was productive to continue research on the virus. Each time, new technologies emerged that allowed the field to advance and become active once again. Today, research on poliovirus is as vibrant as ever. The difficulties encountered in the effort to globally eradicate this virus have allowed research to continue. Nevertheless, work on other picornaviruses has become highly productive, and research on a wide range of cardioviruses, aphthoviruses, enteroviruses, and members of many other genera flourishes. Many questions remain about nearly every stage of the replicative cycle, and an unprecedented array of experimental techniques and reagents are available to address them. Genome-wide RNA interference screens are being applied to picornaviruses, and have already

identified hundreds of cell genes that not only are required for picornavirus infection but regulate replication.^{108,109} It can be anticipated that cellular genes will be involved in all aspects of the picornaviral replication cycle, from receptor binding and entry to macromolecular synthesis, assembly of new virus particles, and release. Studies of these processes will contribute to understanding questions about how the viral RNA is released from the capsid, whether RNA synthesis proceeds in infected cells as has been learned from *in vitro* systems, how replication complexes are produced in infected cells, and how the viral RNA enters the virion and becomes folded to fit in a very small space. Because poliovirus is a model system, its study provides a unique opportunity to address fundamental questions in virology. The polio eradication program has made impressive gains—as of this writing in April 2012 there have been fewer than 47 cases of paralytic disease, and remarkably, India has been polio free for over 1 year. When the time comes for research on poliovirus to cease, the picornavirus field will be ready to move on to other fascinating subjects. As viral discovery in general has greatly accelerated in the past 5 years, the size of the *Picornaviridae* has grown remarkably. With this growth come new opportunities to study fascinating new viral systems, one of which might some day become the next model system for this virus family.

HISTORY

The history of enteroviruses (EVs) is very much the history of poliovirus (PV). In fact, many of the PV milestones are landmarks in the study of EV and, in fact, all of virology.

Poliomyelitis is believed to be an ancient disease. It has been suggested that the depiction of a young man with an atrophic limb on an Egyptian stele from the second millennium bc represents a sequela of poliomyelitis.¹⁹⁷ The first clinical descriptions of poliomyelitis were made in the 1800s, with reports of cases of paralysis with fever. In 1840, von Heine¹⁵³ published a monograph more specifically describing the affliction. His contributions and those published later by Medin²⁷¹ from Sweden led to paralytic poliomyelitis being referred to as *Heine-Medin disease*. Another early report, by Charcot and Joffroy,⁶⁵ described the pathologic changes in the anterior horn motor neurons of the spinal cord in poliomyelitis.

The 1900s began a new era in poliomyelitis investigations and the beginning of an understanding of the infectious nature of this disease. Wickman⁴¹⁸ and others recognized the communicable nature of poliomyelitis, the importance of asymptomatic infected individuals in transmission of PV, and the role of enteric infection in disease pathogenesis. The role of the gastrointestinal tract in the initiation and spread of PV infection was later confirmed by Trask et al.³⁹⁶ In a classic study, Viennese investigators Landsteiner and Popper²⁴¹ proved the infectious nature of poliomyelitis by successfully transmitting the clinical disease and its pathology to monkeys following inoculation of central nervous system (CNS) tissue homogenates from human cases.

Despite this progress, a number of unfortunate misconceptions emerged about poliomyelitis that initially confused scientists and misdirected efforts for control. These misconceptions included a belief that the virus was exclusively neurotropic, that

the nasopharynx was a major site for virus entry into the CNS, and that the virus spread to the nervous system before viremia and by way of the olfactory nerve. As a result of these misconceptions and the failure of several poorly conceived immunization attempts, some with rather disastrous results,³²⁸ an atmosphere of pessimism existed by the middle of the 20th century concerning the eventual control of poliomyelitis, even among scientists working in the field. In 1945, Burnet⁴⁹ wrote, "The practical problem of preventing infantile paralysis has not been solved. It is even doubtful whether it ever will be solved." The eventual realization that virus entered via the oral–gastrointestinal route and that CNS disease followed a viremia did much to boost hopes for effective immunization.³⁶

Building on studies of others, Enders et al.¹⁰⁵ performed a landmark study showing that PV could be propagated in non-neural tissue culture. These investigations had implications for all of virology because they indicated, first, that PV grew in various tissue culture cells that did not correspond to the tissues infected during the human disease, and second, that PV destroyed cells with a specific cytopathic effect. Neutralization tests showed that PV has three serotypes,³⁹ and serologic tests²⁵ confirmed that most infected individuals do not manifest clinical disease. These investigations laid a critical framework for the development of a vaccine, and they clarified a host of confusing data, such as the apparent presence of second attacks of poliomyelitis.

A variety of vaccines were subsequently produced, with the most well known being the Salk inactivated polio vaccine (IPV) delivered via the intramuscular route (licensed in 1955 in the United States) and the Sabin live, attenuated vaccine (oral polio vaccine [OPV]) delivered via the oral route (licensed in 1961–1962). The importance of these vaccines and the individuals who produced them can begin to be realized by noting that more Americans knew the name of Jonas Salk than the president of the United States. The real impact of these vaccines will ultimately be felt with the complete global eradication of poliomyelitis. The eradication will undoubtedly provide a fitting dramatic finale to the compelling story of poliomyelitis.

Poliovirus work has had a continuing significant impact on the field of molecular virology. PV was the first animal virus completely cloned and sequenced,^{227,337} the first RNA animal virus for which an infectious clone was constructed,³³⁶ and the first human virus that had its three-dimensional structure solved by x-ray crystallography.¹⁶⁴ In 1989, Mendelsohn et al.²⁷⁹ identified the PV receptor, CD155, a finding that was followed by the generation of mice carrying CD155 as a transgene.^{234,344}

Coxsackieviruses (group A) were first isolated during poliomyelitis outbreaks in 1947 from the feces of paralyzed children in Coxsackie, New York.⁸⁹ These isolates were obtained by inoculation of suckling mice, the pathogenicity in mice clearly differentiating these viruses from PV. In the following year, the first coxsackievirus (CV) group B was isolated from cases of aseptic meningitis.²⁷⁶ The original CV group A (CVA) isolates produced myositis with flaccid hind limb paralysis in newborn mice, whereas the coxsackieviruses group B (CVB) produced a spastic paralysis and generalized infection in newborn mice, with myositis and involvement of the brain, pancreas, heart, and brown fat.

In 1951, echoviruses were first isolated from the stool of asymptomatic individuals.³⁴⁹ Echoviruses received their name because they were enteric isolates, cytopathogenic in tissue culture, isolated from humans, and orphans (i.e., unassociated with a known clinical disease). Subsequent studies have shown

that echoviruses, in fact, do cause a variety of human diseases. After this period of rapid growth in the number of enteroviruses, there were several decades where new enteroviruses were uncommonly identified. This changed with the introduction of molecular detection methods, and the last 15 years have seen a rapid expansion in the number of recognized enteroviruses. This period of discovery is still in progress.

INFECTIOUS AGENTS

Physical and Chemical Properties

Enteroviruses are distinguished from other picornaviruses on the basis of physical properties, such as buoyant density in cesium chloride and stability in weak acid. Many aspects of enteroviral pathology, transmission, and general epidemiology are directly related to the biophysical properties and their cytolytic life cycle. The infectious virus is relatively resistant to many common laboratory disinfectants, including 70% ethanol, isopropanol, dilute Lysol, and quaternary ammonium compounds. The virus is insensitive to lipid solvents, including ether and chloroform, and it is stable in many detergents at ambient temperature. Formaldehyde, glutaraldehyde, strong acid, sodium hypochlorite, and free residual chlorine inactivate enteroviruses. Concentration, pH, extraneous organic materials, and contact time affect the degree of inactivation by these compounds. Similar inactivation is achieved when virus is present on fomites, although conditions may not be exactly comparable.¹ In general, most reagents that inactivate EV depend on active chemical modification of the virion, whereas most extractive solvents have no effect.

Enteroviruses are relatively thermostable, but less so than hepatitis A virus. Most enteroviruses are readily inactivated at 42°C, although some sulfhydryl reducing agents and magnesium cations can stabilize viruses so that they are relatively stable at 50°C.^{8,99} The relative sensitivity to modest elevations in temperature makes it possible to use pasteurization to inactivate EV in many biologically active preparations.¹⁶⁰

As with other infectious agents, ultraviolet light can be used to inactivate EV, particularly on surfaces. In addition, the process of drying on surfaces significantly reduces virus titers. The degree of virus loss by drying is related to porosity of the surfaces and the presence of organic material.² Many studies of EV inactivation have been conducted using PV as a model enterovirus. A report describing strain-specific differences for glutaraldehyde inactivation among echovirus 25 isolates implies, however, that the assumption that PV is representative of all EV may not be valid.⁶² The inactivation of infectivity may not be directly related to the destruction of the viral genome, because the polymerase chain reaction (PCR) can be used to amplify viral RNA, even after inactivation of virus has occurred.²⁵⁹ This would suggest that reactivation of infectivity may be possible in some circumstances. In fact, some examples of recovered infectivity have been reported through increased multiplicity of infection in cell culture,^{372,443} but the practical significance of these observations is not clear.

Antigenic Characteristics and Taxonomy

As described in Chapter 16, the picornaviruses are among the simplest RNA viruses, having a highly structured capsid with little place for elaboration. Yet, despite the limited

genetic material and structural constraints, evolution within the picornaviruses has resulted in a large number of readily distinguishable members. This variability has been categorized antigenically as serotype.

Each of the serotypes correlates with the immunologic response of the human host, protection from disease, receptor usage, and, to a lesser extent, the spectrum of clinical disease. These correlations, however, have only a partial relationship with the original classification of enteroviruses into polioviruses, coxsackie A or B viruses, and echoviruses, based on biological activity and disease: human CNS disease with flaccid paralysis (poliomyelitis); flaccid paralysis in newborn mice, human CNS disease, and herpangina (coxsackie A viruses); spastic paralysis in newborn mice and human CNS and cardiac disease (coxsackie B viruses); and no disease in mice and (originally) no human disease (echoviruses). Within each of these groups, isolates can be readily distinguished on the basis of antigenicity as measured with antisera raised in animals. The original classification scheme broke down with the identification of viruses serologically identical to known echoviruses that were found to cause disease in mice and humans. This and other inconsistencies led to a numbering of new EV serotypes starting with EV68. These antigenic groupings, which define the serotypes, became increasingly more complicated as the number of different viruses grew. Despite these limitations, the serotype remains the single most important physical and immunologic property that distinguishes the different EVs. Most of the prototype EV strains are maintained in the American Type Culture Collection, Manassas, Virginia, and in many of the World Health Organization (WHO) collaborating reference laboratories.

Despite the importance of the antigenic properties, the introduction of molecular typing methods and a reassessment of the limitations of the old classification scheme led to the development of the current classification system that divides the members of the EV genus into species on the basis of genome organization and sequence similarity as well as biological properties (Table 17.1).

The human enteroviruses are now classified into four species: *Enterovirus A* (EV-A), EV-B, EV-C, and EV-D. In this system, members within an EV species:

share greater than 70% aa [amino acid] identity in the polyprotein, share greater than 60% aa identity in P1, share greater than 70% aa identity in the nonstructural proteins 2C + 3CD, share a limited range of host cell receptors, share a limited natural host range, have a genome base composition (G + C) which varies by no more than 2.5%, share a significant degree of compatibility in proteolytic processing, replication, encapsidation, and genetic recombination.²³⁰

Coding for the capsid proteins, the P1 region provides a reliable correlation between sequence relatedness and the traditional definition of serotype. This also appears to be true for the various individual capsid protein regions, with the exception of VP4; the VP4 sequence does not always correlate with serotype and, therefore, is not reliable for serotype identification.

The molecular studies have also provided a framework in which the EV antigenic relationships can be better understood. These studies suggest that the nucleotide sequence of VP1 can function as an excellent surrogate for the reference antigenic typing methods that use neutralization tests in order to distinguish EV serotypes. VP1 nucleotide sequence identity of at

least 75% (85% aa identity) between an isolate and a serotype prototype strain suggests that the isolate is serotypically identical to the prototype (assuming that the next highest identity with other prototype strains is less than 70%). For example, a capsid sequence identity of 85.4% aa between CVA3 and A8 compared with a mean sequence identity among prototype strains of 71.5% confirmed the antigenic relationships that had previously been described and suggested that these two viruses probably derived relatively recently from a common ancestor.³¹⁸ Similarly, capsid sequences with more than 96% identity confirmed the antigenic relationships between CVA11 and A15 and between A13 and A18;⁴⁶ as a result, CVA15 and A18 have been reclassified as A11 and A15, respectively. In this way, the use of VP1 sequencing studies has supported and clarified early serologic data and also led to proposals regarding the classification of isolates into new EV serotypes.^{312,316}

No general correlation is found, however, between sequence similarities with serotype in genome segments outside of the capsid region because of frequent recombination in the noncapsid regions. For example, sequencing studies have shown that phylogenetic trees constructed from sequences from varying genome regions of members of EV-C and *Poliovirus* have incongruities between the capsid region and noncapsid regions,⁴⁶ suggesting that viruses with a PV capsid may recombine with these CV nonstructural protein coding regions to acquire different nonstructural protein sequences and, similarly, viruses with a CV capsid protein sequence may recombine to acquire different nonstructural protein sequences.²⁵⁵ These findings imply that recombination occurs between PV and other EV-C viruses within the nonstructural protein coding regions, and this shuffling of different nonstructural protein coding regions may lead to serotypes with selective advantages that become dominant. The frequency of recombination in the noncapsid region supports the idea that serotype is defined by the capsid region and that limited correlations likely exist between the serotype of isolates and other phenotypic characteristics not associated with the capsid proteins. The findings also demonstrated that the phylogenetic clustering of prototype strains changes, depending on the nonstructural region that is analyzed.

Recombination within the nonstructural proteins was also found among EV-A and EV-B prototype members with other members of the same species, consistent with their classification into two separate species.^{314,318} An analysis of multiple isolates within several EV-B serotypes³¹⁹ found relatively frequent interserotypic recombination of the noncoding regions, which appeared to occur at least once every 6 years for the isolates that were analyzed. Although no evidence was found of interserotypic recombination within the capsid (perhaps because of structural constraints specific for a particular serotype), intraserotypic recombination within this region appeared to occur.

Additional sequencing studies showed that the 5' untranslated region (UTR) of enteroviruses forms two clusters: the viruses of EV-C and EV-D compose cluster I, whereas EV-A and EV-B compose cluster II.^{46,188}

Sequencing studies have also demonstrated significant similarities between human rhinoviruses and the human enteroviruses, resulting in a reclassification of the human rhinoviruses as members of three different species within the genus *Enterovirus*.²³⁰ Despite the reclassification, the rhinoviruses have several unique properties and are covered separately in this volume (see Chapter 18).

TABLE 17.1 Picornavirus Genera, Species,^a and (Sero)Types

Genera and species	No. of types	Comments
Genus <i>Enterovirus</i>	269	
Human enterovirus A ^b	22	Five have been found only in nonhuman primates
Human enterovirus B ^b	60	Two have been found only in nonhuman primates
Human enterovirus C ^b	21	
Human enterovirus D ^b	4	
Human rhinovirus A ^b	77	
Human rhinovirus B ^b	25	
Human rhinovirus C ^b	49	
Simian enterovirus A	1	
Bovine enterovirus	2	Possible third type detected in sheep
Porcine enterovirus B	3	
Unclassified	5	Detected in nonhuman primates
Genus <i>Hepatovirus</i> ^b	1	
Genus <i>Cardiovirus</i>	12	
Encephalomyocarditis virus ^b	1	
Theilovirus ^b	11	
Genus <i>Kobuvirus</i>	3	
Aichi virus ^b	1	
Bovine kobuvirus	1	Also found in sheep and pigs
Porcine kobuvirus	1	
Unclassified	2	One virus detected in rodents and one in dogs
Genus <i>Teschovirus</i>	11	
Genus <i>Erbovirus</i>	3	
Genus <i>Aphthovirus</i>	11	
Foot-and-mouth disease virus	7	
Bovine rhinitis A virus	1	
Bovine rhinitis B virus	2	
Equine rhinitis A virus	1	
Genus <i>Parechovirus</i>	20	
Human parechovirus ^b	16	Types 1 and 2 formerly classified in genus <i>Enterovirus</i>
Ljungan virus	4	
Genus <i>Sapelovirus</i>	8	
Simian sapelovirus	3	
Porcine sapelovirus	1	Formerly porcine enterovirus A in genus <i>Enterovirus</i>
Avian sapelovirus	1	
Unclassified	3	One virus detected in rodents and two in sea lions
Genus <i>Senecavirus</i>	1	
Genus <i>Tremovirus</i>	1	
Genus <i>Avihepatovirus</i>	3	
Proposed genus Aquamavirus	1	
Proposed genus Cosavirus ^b	4	
Proposed genus Megrivirus	1	
Proposed genus Salivirus ^b	1	
Unclassified picornaviruses	18	Viruses detected in bats, cats, rodents, sheep, birds, fish, and reptiles

^aThe classification scheme shown is from the Picornavirus Study Group of the International Committee on the Taxonomy of Viruses (Knowles NJ, Hovi T, Hyypiä T, et al. Picornaviridae. In: King AMQ, Adams MJ, Carstens EB, et al., eds. *Virus Taxonomy: Classification and Nomenclature of Viruses: Ninth Report of the International Committee on Taxonomy of Viruses*. San Diego: Elsevier, 2011:855–880; and <http://www.picornaviridae.com>). The types that compose the human enterovirus species are listed in Tables 17.4 through 17.7.

^bAt least one virus in the genus or species has been detected in humans.

In addition to the genetic relatedness, many different EV serotypes share some antigenicity. For example, PV1 and 2 share a common antigen, and antigenic relationships also exist between coxsackieviruses A3 and A8, A16 and EV71, and A24 and EV70, and between echoviruses 6 and 30, and 12 and 29. When virions are disrupted by heating, particularly in the presence of detergent, nonsurface antigens are exposed that are shared broadly among many EVs.²⁸⁰

Despite this lack of understanding of molecular variation in virus structure as measured by polyclonal antibodies, high-resolution studies of the virion surface have been particularly useful in identifying the targets of neutralization of EV by monoclonal antibodies.^{165,327} Other less investigated antigenic sites elicit immune responses that are not neutralizing but nevertheless contribute to serotype identity. The observed structure of some antigenic sites has been shown to span non-continuous polypeptide chains, providing an explanation for why antigenicity of the virus is destroyed by disruption of the virion structure.

Antisera raised in animals to each of the enteroviruses are largely type specific and are used to determine serotype in a neutralization assay. The PV neutralizing antibody response is serotype specific, with the exception of some minor cross-reaction between PV1 and 2. A monoclonal antibody has been described that reacts with this shared site that is not found on PV3.⁴⁰³ As noted, heat-disrupted virions, particularly those heated in the presence of detergent, induce antibodies that react with many EVs.²⁸⁰ These broadly reacting antibodies are generally not neutralizing, and at least one of these epitopes has been mapped to the amino-terminal region of capsid protein VP1.³⁶² Although measurable *in vitro* differences are found in antigenic properties among strains within a serotype, the significance of these differences during natural infection has not been determined. Several PVs isolated during outbreaks have demonstrated different antigenic properties when compared with the reference vaccine strains.^{140,186} In all cases, immunity derived from vaccination has been sufficient to provide protection and control of these strains.⁴³ In addition, even in the face of massive immunization campaigns, no antigenic *escape mutants* resistant to neutralization have ever been observed, and successive genotypes of PV have been eliminated. Natural antigenic variants have also been identified with panels of monoclonal antibodies for several nonpolio EVs.^{148,329}

Propagation and Assay in Cell Culture

One of the prominent characteristics of enteroviruses is the cytolytic nature of growth in cell culture. For many years, PV was the prototype of a lytic viral infection. At the microscopic level, infection is usually manifest within 1 to 7 days by the appearance of a characteristic cytopathic effect, which features visible rounding, shrinking, nuclear pyknosis, refractility, and cell degeneration (Fig. 17.1). The earliest effects can be seen in less than 24 hours if the inoculum contains many infectious particles. With fewer virions, however, visible changes are not recognizable for several days, although a sufficient number of cells are infected. In addition, some EVs either do not cause cytopathic effect at all or do so only after several passages. In general, once focal cytopathic effect is detected, infection spreads rapidly throughout the cell sheet with total destruction of the monolayer, sometimes in a matter of hours.

All known EVs can be propagated in either cell culture or in suckling mice. Most of the serotypes can be grown in at least one human or primate continuous cell culture. No cell line, however, can support the growth of all cultivable EVs. Even after many years of experimentation, a few serotypes (e.g., CVA19) can be propagated only in suckling mice. The typical host range of human EV in cell cultures or animals is shown in a broad, generalized way in Table 17.2 and is not clearly associated specifically with a given virus species.²⁷⁵ Infection of target cells depends on viruses binding to specific receptors on the cell surface. Collectively, the EVs use many different receptors. A practical adaptation resulting from the identification and genetic cloning of EV receptors is the introduction of the receptor into animals and cells that do not normally permit virus infection. This approach has resulted in advances in understanding both the pathogenesis of PV infection in a nonprimate animal model system and its practical application in the diagnostic laboratory. The L20B cells, which are murine cells that express CD155, are now used routinely to selectively isolate PV (see Diagnosis) as part of the global PV laboratory network supporting the poliomyelitis eradication initiative.³³³

Infection in Experimental Animals: Host Range

The natural host for all human enteroviruses is the human. Although serologically distinct picornaviruses with the same physical properties as human EV have been found in many animals, human beings do not usually have recognizable infections with these animal EV. On the other hand, some animals are susceptible to experimental infection with human EV. These include nonhuman primates and CD155 transgenic mice for polioviruses, mice and some monkeys for coxsackieviruses A and B, and monkeys for echoviruses. Human EV can infect nonhuman primates, perhaps related to the homology that several simian EVs share with human viruses, but the infections appear to be largely subclinical.^{313,334} Among higher primates, chimpanzees and gorillas appear to be able to acquire PV infection and develop disease from humans through natural exposure.¹⁰⁰ CVB5 is closely related antigenically to the porcine EV causing swine vesicular disease, with about 50% genetic homology over the entire genome. Genetic studies of a number of strains of swine vesicular disease virus, as well as epidemiologic information gleaned from outbreaks, strongly suggest that a human CVB5 was specifically introduced into swine decades ago and led to establishment in this new host.⁴⁴⁸

Although most coxsackie A viruses have been successfully grown in various cell culture systems, isolation from clinical specimens is sometimes unsuccessful, necessitating the inoculation of suckling mice. Inoculation of suckling mice and subsequent virus identification is a process analogous to that of cell culture inoculation. A blind passage in mice may be necessary if the inoculum is of very low titer or, possibly, because passage of the virus is needed for it to adapt to growth in mice. The two groups of coxsackieviruses can be distinguished by the distinct pathology that they cause in mice (Figs. 17.2 and 17.3). With CVA infection, newborn mice develop flaccid paralysis and severe, extensive degeneration of skeletal muscle (sparing the tongue, heart, and CNS), and they may have renal lesions. Death usually occurs within a week. CVB infection proceeds more slowly and is characterized by spastic paralysis and tremors associated with encephalomyelitis, focal myositis, necrosis of brown fat pads, myocarditis, hepatitis, and acinar cell

FIGURE 17.1. Normal and poliovirus (PV)-infected rhabdomyosarcoma (RD) cells and CD155 transgenic mouse L cells (L20B) in culture. **A:** Monolayer of normal RD cells in culture. **B:** RD cell culture showing early stage of cytopathic effect typical of PV infection. Approximately 25% of the cells in the culture show cytopathic effect (especially rounding) indicative of virus multiplication (1+ cytopathic effect score). **C:** RD cell culture illustrating more advanced cytopathic effect (3+ to 4+ cytopathic effect). **D:** Almost 100% of the cells are affected, and most of the cell sheet has come loose from the wall of the culture tube. **E–H:** Similar stages of cytopathic effect are shown as in **A–D**, but in this case L20B cells are infected with PV.

TABLE 17.2 Usual Host Range of Human Enteroviruses: Animal and Tissue Culture Spectrum^a

Virus	Antigenic types ^b	Cytopathic effect		Illness and pathology	
		Monkey kidney tissue culture	Human tissue culture	Suckling mouse	Monkey
Polioviruses	1–3	+	+	–	+
Coxsackieviruses, group A	1–22, 24	±	±	+	–
Coxsackieviruses, group B	1–6	+	+	+	–
Echoviruses	1–33	+	±	–	–
Enteroviruses	68–116	+	+	–	–

^aMany enteroviral strains have been isolated that do not conform to these categories.

^bNew types, beginning with type 68, are now assigned enterovirus type numbers instead of coxsackievirus or echovirus numbers. Types 68–116 have been identified.

Large zone of myocardial necrosis at apex of left ventricle (×170). **B:** Brain. Rarefaction after necrosis in cerebrum (×140). **C:** Brain. Encephalitis showing marked perivascular cuffing and leptomeningitis (×190). **D:** Fat lobules. Interlobular edema and acute necrotizing steatitis, illustrating the selective destruction of the peripheral parts of the lobules, which are shown as pale margins, with preservation of the central parts, which are shown as dark fuchsinophilic areas (×72). (From Melnick JL. Current status of poliovirus infections. *Clin Microbiol Rev* 1996;9[3]:293–300, with permission.)

FIGURE 17.4. Dendrogram of genus *Enterovirus*. The figure illustrates the phylogenetic relationship among the prototype strains (see Tables 17.4 through 17.7) within the genus *Enterovirus* and the distinct grouping of isolates into each of the species of viruses that affects humans and other related animal enteroviruses based on the amino acid sequence of the P1 (capsid) coding region of the genomes. Species: EV-A (formerly *Human enterovirus A*); EV-B (formerly *Human enterovirus B*); EV-C (formerly *Human enterovirus C*); EV-D (formerly *Human enterovirus D*); RV-A (formerly *Human rhinovirus A*); RV-B (formerly *Human rhinovirus B*); EV-E (formerly *Bovine enterovirus*); EV-G (formerly *Porcine enterovirus B*); EV-H (formerly *Simian enterovirus B*). Not shown: EV-F (*Bovine enterovirus 2*), EV-J (*Simian virus 6* and related viruses), and RV-C. (Data from M. S. Oberste.)

pancreatitis. Echoviruses, except for some isolates of echovirus type 9, do not generally cause disease in mice.

Other Human Picornaviruses

In addition to the enteroviruses, rhinoviruses (Chapter 18), and hepatitis A (Chapter 19), other picornaviruses that infect humans have been recently discovered or previously considered to be enteroviruses and reclassified as a separate genus (Table 17.1). These genera are genetically distinct from the EV genus (Fig. 17.4) but share some physical and structural similarity with EV. On the basis of a very low genetic relationship, differences in viral proteins and processing, and a novel 2A protease, echoviruses 22 and 23 were reclassified as a new genus, *Parechovirus*. Additional members of this genus exist, including additional serotypes of human parechovirus,¹⁹² as well as a separate species first isolated in Swedish bank voles, Ljungan virus; Ljungan virus has been associated with diabetes in its natural host and may have a possible role in human disease.³⁰² The human parechoviruses (HPEVs) cause a similar spectrum of illnesses as the EVs and can often be detected in cerebrospinal fluid (CSF) from meningitis cases at a frequency similar to that of the EVs.^{409,422} Serologic studies suggest that HPEV infection occurs at an early age, as most children were seropositive by the age of 2 years.^{3,198,385} HPEV3 has been associated with sepsis-like illness and CNS disease in infants.^{32,41}

Another distinct picornavirus genus associated with human infection is *Kobuvirus*.⁴³⁴ Although little information is currently available about this virus, it appears that it is often associated with gastroenteritis in young children and infection

is common. Members of the genus *Cardiovirus* have also been associated with disease in humans, but they do not appear to be a major cause of human illness.^{301,309} Viruses in the proposed genus *Salivirus* are related to kobuviruses and have also been associated with gastroenteritis in humans.^{167,250} Another proposed genus, *Cosavirus*, has been detected at a relatively high frequency in stool, but there is no known association with disease. What is notable about all of these newer genera is that the currently available molecular reagents for the detection of EV do not detect these viruses (see Diagnosis).

PATHOGENESIS AND PATHOLOGY

Entry into the Host

Virus infection normally requires that the virion can attach to the cell surface, and it was long imagined that each virus would have a single receptor. For poliovirus, at least, this may be the case: the virus binds to the poliovirus receptor (PVR,²⁷⁹ now named CD155), a transmembrane glycoprotein in the immunoglobulin superfamily that mediates adhesion of natural killer (NK) cells, and triggers their effector functions. PVR (human CD155) appears to be the major factor regulating the virus's natural host range, which is limited to humans and Old World primates. CD155 homologs/orthologs have been identified and characterized in mice²⁸⁹ and in New World monkeys; the extracellular domains share ~70% amino acid homology with hCD155, and these homologs do not support efficient PV binding or infection. Several laboratories have generated transgenic mice that express PVR, and in many of the resulting models, PV was shown to induce neurologic disease and paralysis following parenteral administration.^{82,117,189,233,279,295,342–344,449} However, oral administration did not cause disease even when the PVR transgene was regulated by a promoter that drove protein expression in enterocytes and microfold (M) cells; PV appeared to bind to the intestinal cells, but productive infection was not observed following oral inoculation of greater than 10⁸ plaque-forming units/mL (pfu) of virus.⁴⁴⁹ These findings are consistent with studies of humans and susceptible primates, in which hCD155 expression has been identified in many tissues, but productive infection is limited largely to the CNS. Thus, factors other than PVR expression play a key role in determining *in vivo* tropism.

It is now generally accepted that some viruses, or viral strains, may have more than one receptor, perhaps expanding their potential host range. EV71, most frequently associated with hand-foot-and-mouth disease in children but capable of causing devastating neurologic pathology,³⁸¹ has at least two receptors: scavenger receptor B2⁴³⁵ and P-selectin glycoprotein ligand-1.³⁰³ Indeed, some viruses appear to interact with two different surface molecules on a single cell, perhaps in series, with one protein acting as the binding moiety, before “handing over” the virus to a second protein that facilitates its entry into the cell. This is thought to occur for some CVBs that bind to decay accelerating factor (DAF, CD55) but then must interact with another protein, the coxsackievirus and adenovirus receptor (CAR), in order to enter the cell.

Site of Primary Replication

Human enteroviruses are spread by the fecal–oral route and respiratory droplets, so systemic infection requires the virus to

cross the gastrointestinal wall, most of which is lined with epithelial cells that form a barrier to invasion. Perhaps surprisingly, given the many years of study, the primary site of PV infection and replication in the intestine remain unknown. PV has been identified in lymphoid tissues, such as the tonsils,³⁶ and in lymphoid aggregates, commonly termed Peyer's patches (PPs), that are present in the ileum of the small intestine. PPs are overlaid with a specialized follicle-associated epithelium (FAE) that contains M cells, which can transport certain molecules from the gastrointestinal lumen, across the epithelial layer, and into cells in the PP. Some studies suggest that PV may replicate within these epithelial cells and lymphoid cells,²⁰⁴ while others suggest that the virus may be transcytosed through the M cell, subsequently establishing infection in an unidentified cell in the PP.³⁷⁵ The cells in which CVB initially replicates are also uncertain; this issue is further clouded by the predominant use, in mouse models, of the intraperitoneal route of infection. Human rhinovirus (HRV) infects epithelial cells of the airways. Infection of the nasal epithelium causes few detectable pathologic changes, even if rhinitis is quite severe, and—as is true for many virus-induced diseases—many of the symptoms appear to be caused by the host response rather than by direct virus-mediated tissue damage.^{420,421}

Spread in the Host

Following replication in the alimentary tract, PV enters the blood, thereby potentially gaining access to all tissues; however, in normal hosts, viral replication is highly restricted, being readily detected mainly in the CNS.³⁶ PV can enter the CNS in two ways: first, from the blood—the virus is thought to be able to cross the blood brain barrier (BBB), perhaps independently of the PVR,⁴³⁷ thereby accessing the CNS parenchyma; and second, by retrograde axonal transport, in which the virus (apparently in the form of an intact virion) ascends the neuronal axon, perhaps in endosomes, and uncoating begins when PV reaches the cell body.^{320–322} This may underpin provocation poliomyelitis, a phenomenon in which a traumatized limb is more susceptible to paralytic polio. The trauma may be directly associated with the virus, as reported in 1935, when it was noted that paralysis first appeared in (or was most severe in) the limb that had received an intramuscular inoculation of “pre-Salk” polio vaccine.²⁴⁴ Such inoculation poliomyelitis also was observed in the “Cutter incident,” when an incompletely inactivated Salk vaccine was administered.²⁹⁷ However, provocation poliomyelitis does not require that trauma and virus be administered to the same limb; when PV was administered intravascularly to monkeys that had received innocuous injections into one limb, paralysis was more likely to develop in the injected muscles.³⁸ Provocation poliomyelitis also has been reproduced in a mouse model.¹³⁹ Mechanisms other than retrograde axonal transport may contribute. For example, the peripheral trauma may increase the permeability of the BBB locally, in the region that innervates the injured muscle; this could explain why provocation poliomyelitis still occurs in traumatized limbs despite scission of the ipsilateral peroneal muscle.²⁹⁶ Dissemination of CVB and other enteroviruses appears to occur largely by the hematogenous route. Viremia is frequently found, when sought; this is true even in rhinovirus infection of normal or asthmatic children,⁴³² in which spread to the lower respiratory tract was thought to occur by more direct means.

Cell and Tissue Tropism

It has been proposed that the observed *in vivo* tropism of PV for the CNS may result from differing efficiencies of viral internal ribosome entry site (IRES) utilization by the various cell types. However, this explanation appears to be incorrect; the PV IRES is equally functional in many cell types *in vivo*, including those that do not support virus replication in the living animal.²¹¹ Rather, the explanation may lie in the ability of an infected cell (or tissue) to respond to type I interferons (T1IFNs). Following PV infection, PVR transgenic mice lacking the receptor for these key antiviral cytokines developed severe lesions not only in the CNS but also in the liver, spleen, and pancreas.¹⁹⁰ Thus, in immunocompetent PVR transgenic mice (and, by extension, in the natural hosts), the absence of apparent PV infection in most hCD155+ peripheral tissues may result from these cells' being able to mount rapid and strong T1IFN responses; and the apparent neurotropism of the virus in immunocompetent hosts may reflect a reduced or delayed T1IFN response within the CNS.¹⁹⁰

CVB3 can cause pancreatitis, myocarditis, and meningoencephalitis. Enteroviruses, and especially CVB, have been implicated in up to one-third of human pancreatitis cases.^{22,326,404} In the mouse model, the pancreas appears to be the first major site of abundant CVB3 replication, with virus titers reaching $\sim 10^4$ pfu/gram after only 12 hours, and $\sim 10^{10}$ pfu/gram at 24 hours postinfection.^{277,278} As shown in Figure 17.5A, there is a large inflammatory infiltrate and widespread destruction of the exocrine pancreas, but the islets of Langerhans remain apparently unaffected. Transmission electron microscopy (Fig. 17.5B and C) reveals, in infected acinar cells, nuclear pyknosis and the accumulation of small double-membraned autophagy-like vesicles, also termed compound membrane vesicles, which are characteristic of enterovirus-infected cells. CVB4 also causes pancreatitis,^{339,340,406} the severity of which depends on the virus isolate that is used; a single amino acid change in VP1 appears to be largely responsible for switching the phenotype from mild pancreatitis to a more severe form.^{51,142} CVB has been found in acinar cells but not in islets of Langerhans^{356,407,410} by immunohistochemistry^{23,406} and by *in situ* hybridization.^{23,407,410} CAR expression correlates with the observed pathology: the receptor messenger RNA (mRNA) is expressed at very high levels in acinar cells but not in the pancreatic ducts or the islets of Langerhans (204), consistent with the observation that CVB-infected mice do not develop hyperglycemia.^{277,338} Cre recombinase-mediated deletion of CAR from the pancreas confers substantial, albeit incomplete, protection against organ damage during CVB infection.²⁰³

A role for EV-B, and in particular CVB, also has been suggested in type 1 diabetes (T1D), and evidence is available to support this notion.^{40,75,341} Several studies have implicated antibody or T-cell cross-reactivity between CVB and host proteins to explain the observed correlations.^{107,179,180,299,300,353} The innate immune system, too, may be involved; a human genome-wide scan for nonsynonymous single nucleotide polymorphisms, comparing healthy individuals to diabetic patients, identified MDA5 as a T1D susceptibility locus.³⁷⁹ However, despite many years of study, a causal role for CVB (or any enterovirus) in T1D has not been convincingly demonstrated in humans, and the issue remains controversial. It is possible that, as has been proposed for pancreatitis, enteroviruses are a co-factor in T1D, very rarely initiating disease in healthy islets but tipping

FIGURE 17.5. Histopathology and electron microscopy of coxsackievirus B3 (CVB3)-infected mice. **A:** Inflammatory infiltrate of pancreas with destruction of the exocrine pancreas but sparing of the islets of Langerhans. **B:** Transmission electron microscopy of infected acinar cells showing nuclear pyknosis. **C:** Further magnification of **B** showing accumulation of small double-membraned autophagy-like vesicles. **D:** Infected heart myocardium showing inflammatory infiltrate that contains predominantly macrophages, T cells, and natural killer cells.

the balance in individuals who—unbeknownst to them—have ongoing islet inflammation and are in prediabetic status.

CVB has long been considered one of the principal causes of viral myocarditis,⁸¹ and this view has been confirmed in several recent reports.^{16,106,262,264,266} The inflammatory infiltrate (Fig. 17.5D) contains predominantly macrophages, T cells, and natural killer cells. Several mechanisms have been proposed to explain CVB-mediated cardiomyocyte destruction. The first is direct, virus-mediated damage. Cardiomyocytes can be infected *in vitro*,^{152,206} and infected cells are rapidly lysed.¹⁵⁸ These *in vitro* findings are corroborated by *in vivo* ultrastructural studies of myocardial tissue, which show clear evidence of virus infection of cardiac muscle cells and cell death.^{131,163,228} The second proposed mechanism is immunopathologic damage. The inflammatory infiltrate contains CD8+ T cells, natural killer cells, and macrophages,^{67,129,156,370} and other studies have implicated $\gamma\delta$ T cells in CVB pathogenesis.^{174–176,178} Finally, studies have implicated autoimmunity in CVB-triggered myocarditis.^{176,299,353–355} One potential means by which this could occur is via molecular mimicry (i.e., immunologic cross-reactivity between viral and heart proteins), and there is evidence

that this occurs at both the antibody^{121,122} and T-cell^{176,177,181} levels. However, recent studies in mice that lack CAR expression only on cardiomyocytes casts doubt on the importance of molecular mimicry in CVB-induced myocarditis. Thus, virus replication in the heart is a prerequisite for myocardial destruction, and this is difficult to reconcile with molecular mimicry; these data do not, of course, exclude a role for autoimmunity induced by other means, for example, by virus-driven exposure of sequestered cardiac antigens.

Immune Response

Innate Immunity

The innate immune response plays a central role in regulating virus infection, as illustrated earlier by the important role played by T1IFNs in regulating PV tissue tropism and pathogenesis. RNA viruses may trigger one (or more) of at least three sensor groups:²⁰⁸ Toll-like receptors (TLRs), retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs), and NOD-like receptors (NLRs, some of which assemble into larger structures termed inflammasomes). The interactions between enteroviruses and NLRs have not been reported, so

FIGURE 17.6. Signaling through Toll-like receptors (TLRs) during enterovirus infections. TLR4 on human pancreatic cells is triggered by infection. TLR3 senses double-stranded RNA (dsRNA) molecules and a strong TLR3-triggered response may protect against enteroviral myocarditis. Other internal TLRs also can contribute to the control of coxsackievirus B (CVB) infections.

herein we focus on the first two sensor groups. Triggering of TLRs and RLRs alters the expression of hundreds of genes including a variety of cytokines, chemokines, and other proteins, some of which can directly counter virus infection (e.g., protein kinase regulated by RNA [PKR, discussed later] and type I interferons), while others may regulate the development of the adaptive antiviral immune response. The roles of cell surface and internal TLRs during enterovirus infections have been evaluated in the CVB model (Fig. 17.6). TLR4 on human pancreatic cells is triggered by CVB4,³⁹⁸ and TLR4 knockout (KO) mice infected with CVB3 show reduced virus titers and myocarditis.¹⁰⁹ A comparison of male and female mice confirmed that TLR4 signaling was correlated with the severity of myocarditis.¹¹⁸ However, the administration of TLR4 stimulants such as lipopolysaccharides (LPSs) greatly increased the severity of CVB-induced myocarditis, suggesting that CVB-mediated triggering of TLR4 *in vivo* is likely to be submaximal.^{242,346} TLR3 senses double-stranded RNA (dsRNA) molecules, which are commonly produced during the replication of RNA viruses.¹³ One study of CVB4 infection of TLR3-deficient mice suggested that TLR3 was almost indispensable for the innate response to this virus³⁴⁷ and, when compared to wild-type (wt) mice, TLR3KO mice showed increased mortality and developed more severe myocarditis following CVB3 infection.^{298,416} Genomic screening of patients diagnosed with enteroviral myocarditis or dilated cardiomyopathy (DCM) revealed two TLR3 sequence variants, both of which showed reduced responsiveness to ligand;¹²⁰ this suggests that a strong TLR3-triggered response may protect against enteroviral myocarditis. Other internal TLRs also can contribute to the control of CVB infections. For example, human cardiac inflammatory responses to CVB are reported to be dependent largely on TLR7 and TLR8,³⁹⁷ both of which recognize single-stranded RNA (ssRNA) and other small molecules.¹⁵¹ Contrary to the reported beneficial effects of a strong TLR3 response to enteroviruses, a strong TLR8 response may be associated with adverse outcomes in patients with enterovirus-associated DCM.³⁶⁵ Autophagy is up-regulated by TLRs, and the most potent pro-autophagic effects are mediated by ssRNA/TLR7 signaling.⁹¹ Electron microscopic (EM) studies of poliovirus-infected cells revealed an association between PV and double-membraned intracellular vesicles,⁸⁸ subsequently shown to be autophagy related.³⁶⁸ Extensive membrane remodeling occurs in a poliovirus-infected cell, mediated by the viral 2BC and 3A proteins,³⁸³ and the resulting vesicles carry several autophagosome-related proteins.^{391,392} A similar relationship between CVB and autophagic vesicles has been reported,¹³⁴ and there is a marked increase in double-mem-

bran structures within CVB-infected cells, both in tissue culture^{424,441} and *in vivo*.²¹⁴ Although autophagy is generally thought to support the replication of these viruses, to date, the effects have been determined only in tissue culture cells and are extremely modest; inhibiting autophagy in cells infected with PV,¹⁹³ CVB3,⁴²⁴ CVB4,⁴⁴¹ or EV71¹⁷³ reduces production of each of these viruses by only 1.5- to 4-fold. To date, few studies have evaluated autophagy during enteroviral replication *in vivo*.

Three RLRs have been identified: RIG-I, MDA5 (melanoma differentiation-associated gene 5), and LGP2 (laboratory of genetics and physiology 2). Unlike TLRs, these proteins are expressed in most cell types. All are activated by nucleic acids, and all are cytosolic, although it has been reported that RIG-I co-localizes with F-actin, and thus is associated with the cytoskeleton.²⁹³ Many RNA viruses produce abundant dsRNA and ssRNA with 5' triphosphate and, therefore, strongly activate RIG-I. In the absence of RIG-I, the innate response to several RNA virus families is abrogated.²⁵⁷ The 5' terminus of an enteroviral RNA lacks the 5' triphosphate moiety, instead bearing a modified protein (VPg), and, for this reason, these viruses do not stimulate RIG-I. Infected cells appear to rely largely on MDA5 to alert them to the presence of picornaviral RNA. This sensor is tripped by the cardiovirus encephalomyocarditis virus (EMCV),^{127,210} and two recent publications using MDA5 knockout mice suggest that enteroviruses, too, trigger MDA5 signaling.^{183,414} MDA5, like RIG-I, is degraded in poliovirus-infected HeLa cells, providing one possible mechanism by which enteroviruses might paralyze the innate immune response.²⁸ However, the observation that MDA5 deficiency has a marked effect during CVB3 infection suggests that, if MDA5 degradation occurs in CVB-infected cells, the process does not prevent MDA5-mediated triggering of the innate response.

At least two observations have been made that may be relevant to both TLR- and RLR-mediated responses to CVB (and, possibly, other enteroviruses). First, many cells—exemplified by macrophages and dendritic cells—are phagocytic and engulf dead or dying cells. Thus, although human dendritic cells (DCs) cannot be productively infected by CVB,²³⁹ these cells can consume debris from CVB-infected cells, thereby potentially introducing viral materials to the cytosolic and intravesicular sensors, potentially inducing an antiviral state in the DCs.²³⁸ Second, as well as degrading the sensors themselves, some enteroviruses can interrupt the downstream signaling upon which the innate response depends. Signaling via TLR3 and the RLRs rely, respectively, on proteins named TRIF and MAVS, both of which are degraded in CVB-infected cells, apparently by the viral 3C protease.²⁹²

NK cells, which are part of the innate response to many infections, are important in protecting against CVB-induced pancreatitis in the mouse model.⁴⁰⁸ The importance of NK cells in combating human enteroviral infections is unknown, but human NK cells can produce interferon- γ (IFN- γ) in response to CVB-infected cells.¹⁸²

Adaptive Immunity

Antibodies and CD8+ T cells together provide a strong antigen-specific barrier against virus infections. Under normal circumstances, these two arms of the adaptive response complement each other. However, members of the *Enterovirus* species appear to be an exception to this general rule. Patients with X-linked agammaglobulinemia are highly susceptible to enteroviral infections,²⁸² and after receiving live poliovirus vaccine, such individuals may continue to shed virulent poliovirus for up to ~20 years.^{219,267} The near-absolute requirement for antibodies in protecting against enteroviruses has been confirmed in an animal model of CVB3 infection, using B-cell knockout (BcKO) mice; these mice cannot eradicate the virus, and high titers are present in many organs.²⁷⁸ These observations suggest that, for agammaglobulinemic hosts infected with an enterovirus, there may be some deficit in the backup system that, for most viruses, is provided by CD8+ T-cell responses. This may, in part, explain why most studies of enteroviral infections, in mouse and man, have identified strong antibody responses, while CD8+ T-cell responses—so easily detected in most virus infections—are weak (if detected at all). The enterovirus genus is large, and the adaptive responses to only a select few enteroviral species will be discussed later.

HUMAN ENTEROVIRUS A

The best-studied pathogen in this species is EV71. The virus triggers an immunoglobulin M (IgM) response that is detectable as early as 2 days postinfection,³⁹⁹ as well as a strong neutralizing IgG response that recognizes epitopes in the N-terminal segment of VP1.³⁸⁷ Neutralizing antibodies, when transferred to uninfected neonatal recipient mice, are able to protect against a lethal challenge infection.⁴⁴⁵ Studies of knockout mice showed that B cells, in particular, were important for survival following EV71 infection, and B-cell-deficient mice treated with virus-specific antibody either before or during EV71 infection had lower virus titers, less severe disease, and lower mortality.²⁵³ Memory T-helper 1 (Th1) CD4+ T-cell responses specific for three epitopes in VP1 have been identified in EV71-positive individuals,¹¹⁶ but no CD8+ T-cell epitopes have been reported.

HUMAN ENTEROVIRUS B

CVBs are the best-studied pathogens in this species and, as described earlier, can trigger severe acute and chronic diseases including myocarditis, DCM, pancreatitis, and aseptic meningitis. Infection by these viruses triggers a rapid and strong neutralizing antibody response. Virus-specific IgM appears during the first week of infection, followed by a strong neutralizing IgG response. The CVB3-specific IgM titer wanes over time, but IgG antibodies persist.²⁵⁶ Work in T-cell-deficient (nude) mice indicates that at least some of the CVB-specific antibody response is T-cell independent,^{150,364,426} although some studies suggest that CD4+ T-cell help may be important for the induction of strong neutralizing antibody responses.²⁴⁶ B cells appear to be targeted by CVB²⁷⁸ and may provide a reservoir for the virus during persistent CVB infection. Viral RNA-positive cells, most probably B cells, can be found in the splenic follicles and

germinal centers;^{14,195,207,229,278} approximately 1% of B cells are infected with CVB3 *in vivo*, and these cells may accelerate the systemic distribution of virus.²⁷⁸ T cells can help control CVB infection, although much less effectively than antibodies. *In vivo* analyses of CVB-specific T cells has been challenging because these viruses, despite replicating to high titers in mice, induce remarkably weak CD8+ T-cell responses.^{378,213a} Nevertheless, some responses can be identified, exemplified by CD4+ T-cell responses against epitopes expressed by CVB4.^{143,144} CD8+ T-cell responses are particularly meager. Epitopes in several viral proteins have been identified in human studies, but their detection required ~2 weeks of *in vitro* peptide antigen restimulation.⁴¹⁶

HUMAN ENTEROVIRUS C

This species contains a number of coxsackie A viruses, but the most important pathogen is PV, which induces a strong neutralizing antibody response that is necessary to control the infection. Virus infection and vaccination induce strong and long-lasting humoral responses,⁷⁹ but the immunity is not sterilizing and secondary infections of the gut can occur. Susceptibility to such reinfections, and subsequent shedding of PV, may be controlled by IgA.⁴⁸ PV-driven T-cell proliferation has been observed in infant vaccinees, and the responses appear to be cross-reactive across different enteroviruses.²⁰² However, PV-specific T-cell responses in OPV-vaccinated infants may be weaker than those in adults.⁴⁰⁵ OPV induces major histocompatibility complex (MHC) class II-restricted memory CD4+ T-cell responses targeted to epitopes in all four capsid proteins.³⁷⁷ CD8+ T-cell responses to PV vaccination are long-lived but, as is true for most CVB-specific responses, they became detectable only after several rounds of *in vitro* restimulation, suggesting that T-cell numbers *in vivo* were low.⁴¹³ Mice are not naturally infected by PV, but PVR-transgenic (PVR-Tg) animals have allowed the analysis of T- and B-cell responses and their roles in antiviral protection. Adoptive transfer of PV-primed B cells together with a VP4-specific CD4+ T-cell clone protected PVR-Tg mice against a lethal challenge of PV, but neither cell population alone was protective, indicating that the virus-specific B cells required T-cell help.²⁶⁵

Release from Host

Virion assembly and RNA packaging of enteroviruses remain very poorly understood. Although enteroviruses are generally considered to be highly lytic—and, therefore, released from cells upon their lysis—there is some evidence from cell culture studies consistent with PV release by nonlytic means.^{330,401} It has been proposed that autophagy-mediated release of PV may occur, permitting the virus to exit a cell in a noncytolytic manner;¹⁹³ this proposed mechanism has, memorably, been termed AWOL (*autophagy-mediated exit without lysis*).³⁹⁰

Virulence

Viral virulence is a complex interplay between virus and host, and some of the contributing elements, such as receptor distribution and host responses, have been discussed earlier. Here, we will focus on selected enteroviral sequences and proteins and their contributions to a virulent phenotype. Wild-type PV is more neurovirulent than the attenuated viruses that constitute the oral vaccine, and studies have identified, in all three PV serotypes, changes in the 5' noncoding region that can alter neurovirulence. For example, sequence comparison between the attenuated Sabin 3 virus and revertants from cases of

vaccine-associated poliomyelitis showed that a single U-C change in the viral IRES, at position 472, conferred a growth advantage in the human intestine and resulted in increased neurovirulence, although, on its own, the change was insufficient to confer full neurovirulence;¹⁰⁸ a second change, leading to an amino acid substitution in VP3, almost completely restored virulence.⁴¹⁷ Mutations in the IRES of PV types 1 and 2 also modulate the neurovirulent phenotype.^{212,260,261} The *in vivo* neuroattenuating phenotype imposed by changes in the IRES, together with tissue culture studies showing apparent cell-specific effects of the IRES mutations,¹⁴⁶ led to the proposal that neuroattenuation might be explained by a neuron-specific reduction in usage of the mutated IRES. However, *in vivo* analyses have demonstrated that, while the Sabin 3 IRES sequence is indeed less effectively utilized in neurons, this defect also is observed in other cells and tissues.²¹² Thus, another explanation was sought. The importance of T1IFNs in modulating PV neurovirulence *in vivo* has been described earlier. Cardiovirulence in CVB3 also has been mapped to various locations in the 5' nontranslated region (NTR), ~80 to 240 bases from the 5' end of the genome,^{64,104,400} although the capsid region, too, plays a part.³⁹⁵ In contrast to the extensive mapping of the limits of, and functional domains within, the PV IRES, analysis of the CVB IRES has been limited.

Persistence

Although both PV and CVB are rapidly cytolytic in many of the cell types that they infect, both viruses can establish persistent or chronic infection in tissue culture.^{78,119,269,331} In neuroblastoma cells, PV persistence is associated with accrual of mutations in the capsid region,³³⁰ and for both PV and CVB, moving from a cytolytic to persistent phenotype in cell culture may be inversely related to the capacity of the virus to adsorb to the receptor and/or to the level of receptor expression.^{53,240} It recently has been reported that, during persistent infection of cultured cells that express low levels of CAR, CVB accumulated changes in the capsid that allow the variant virus to bind to novel (non-DAF, non-CAR) molecules, and this more promiscuous activity conferred a replicative advantage upon the variant.⁵² Cellular factors contribute to the establishment of PV persistence.¹²⁶ Cell cycle status may play a role in the case of CVB, which does not replicate efficiently in tissue culture cells rendered quiescent by drugs or by serum starvation but undergoes productive and cytolytic replication when the cell cycle is triggered.^{112,113}

Enteroviral persistent infections can take place under two general scenarios. First, a chronic productive enterovirus infection can occur in immunocompromised hosts. As noted earlier, agammaglobulinemic individuals who receive oral polio vaccine may retain, and excrete, the virus for many years. One study of individuals with primary immunodeficiency who had developed vaccine-associated paralytic poliomyelitis found that approximately one in five secreted vaccine-derived PV at 6 months after their last OPV dose, but this frequency declined to 0% when the interval was 10 years.²²² The low prevalence of the underlying condition means that such persons are rare; only ~40 such individuals have been identified.⁴²⁹ Fortunately, a more common potential cause of immunosuppression, human immunodeficiency virus (HIV) infection, seems not to correlate with PV persistence/shedding.^{24,157} Second, immunocompetent hosts may carry virus

(or at least viral RNA) for many years. Given the frequency of enteroviral infections, it is reasonable to suppose that this is the more common of the two types of enterovirus persistence. In the vast majority of cases in which enteroviral persistence *in vivo* has been reported in immunocompetent hosts, infectious virus was not identified; rather, viral materials (most commonly RNA) were reported and infectious particles, if sought, were not found. CVB RNA has frequently been detected by PCR in many analyses of cardiac biopsies from individuals with DCM^{20,21,45,232} or inflammatory peripheral myopathy.⁴⁴ From results obtained in a murine model of polymyositis, the authors concluded that the RNA was maintained in double-stranded form, with little indication of virus mutation/evolution.³⁸⁶ However, recent analyses of CVB3 genomes isolated from the hearts of persistently infected mice suggest that CVB persistence *in vivo* may be dependent upon the deletion of nucleotides at the 5' end of the genome.²²⁶ Several deletions were reported, some extending to nucleotide 49, and all affecting the 5' cloverleaf structure that is considered vital for RNA replication. Importantly, the materials were infectious; although replicating very slowly, they could be maintained in culture and did not require a helper virus. The VPg protein was present on several of the deletion mutant genomes and, notably, ~25% of RNA encapsidated into virions was negative sense. The authors proposed that the encapsidation of negative strands might occur because the terminal deletions, by altering RNA replication, markedly reduced the ratio of positive to negative strands. Similar 5' terminal deletion variants subsequently were identified in CVB3 that had been passed in primary tissue culture cells²²⁵ and, critically, in a CVB2 genome isolated from the heart of a human who had succumbed to enteroviral myocarditis.⁶³ The poor infectivity of these mutated viruses may explain why infectious virus was not identified in the vast majority of previous studies in which enterovirus RNA was found. To date, there is no evidence to suggest that these terminally deleted variants can be transmitted under normal circumstances.

EPIDEMIOLOGY

Demographics

Despite the nearly ubiquitous nature of EV infections and the wide variety of clinical presentations, the demographics of the various infections and diseases have some consistent characteristics. In particular, several factors, including age, sex, and socioeconomic status, have largely predictable effects.

One of the most important determinants of EV infection outcome is age. Different age groups have different susceptibilities to infection, severity of illness, clinical manifestations, and prognoses following EV infection. Understanding these age effects on outcome of infection is complicated by the widely divergent prior history of infection and resulting immunity. Nevertheless, it is possible to make certain generalizations.

The largest amount and duration of virus shedding occurs on primary infection with a given EV serotype. Because infection is so common, most primary infections occur during childhood. For these reasons, young children are probably the most important transmitters of EV, particularly within households. The greater exposure of children to virus during infection may make them more likely to have significant clinical

symptoms. For example, in outbreaks of meningitis, children typically have higher rates of disease than adults.^{134,191} Most studies, however, do not separately determine age-specific infection rates and disease rates, and the relative rates at which adults are infected are not generally known.

The incidence of poliomyelitis is relatively low for the first 4 to 6 months of life in countries in which control through vaccination has not yet been achieved, because of the frequent presence of protective maternal antibody. In these countries, an increased incidence is seen of paralytic disease in children older than 6 months compared with children in wealthier developed countries, presumably related to an earlier exposure to virus as a result of poor sanitary conditions. Ironically, areas with improved hygiene may have a decrease in infant exposure, leaving an older (unexposed) population susceptible to epidemic disease, with high rates of paralytic disease during an outbreak.³³⁵ Adults are more likely to be severely affected in both developing and developed countries, tending to acquire paralytic poliomyelitis rather than nonparalytic CNS disease (i.e., aseptic meningitis), abortive illness, or asymptomatic infection.^{56,57,170} The reason for the increase in severity later in life is unknown. A possible reason relates to the finding that fast axonal flow, which appears important in the spread of PV within the CNS,²⁰⁰ increases with age. In addition, it may be that CD155 expression or host factors important in replication change with age.

Severity of a number of enteroviral diseases besides poliomyelitis may be strikingly age related. An indirect indication is that a delay in first infection with a number of EVs increases risk of more severe disease. For example, exanthema associated with CVA and echoviruses are for the most part milder in children than in adults. On the other hand, some EVs cause more severe disease in newborns than in older children and adults, possibly inducing a fulminant *viral sepsis* with myocarditis, encephalitis, and sometimes death (see Clinical Features: Neonate and Infant Disease).^{68,194} In addition, recent outbreaks of hand-foot-and-mouth disease caused by EV71 have been associated with a significant CNS complication, fatal brainstem encephalitis, that was restricted largely to young children (Table 17.3) (see Clinical Features: Meningitis and Encephalitis).^{235,258,428}

In general, encephalitis and aseptic meningitis caused by EV appear to be most frequent among those 5 to 14 years of age rather than those older or younger. In a 10-year surveillance summary from the United States,²⁸⁶ adults tended to be overrepresented among cases of severe disease (paralysis, encephalitis, meningitis, carditis) when compared with the age distribution of the EV-infected population as a whole. In another study, the mean age among patients with CVB meningitis (7.7 years) or pericarditis (9.9 years) was greater than the mean age of patients with CVB gastroenteritis (1.3 years).⁹⁶

Enterovirus infections are more prevalent among persons of lower socioeconomic status and those living in urban areas.^{145,196} In a study utilizing active surveillance of healthy children for EV infections in West Virginia during 1951–1953, the rate of isolations among children in a lower socioeconomic setting was two- to sevenfold higher than among children in a higher socioeconomic setting.¹⁶⁸ A similar study in Ghana during 1971–1973 further indicated that EV isolations were significantly more frequent among children in areas with poorer sanitation and in urban areas during both rainy and dry seasons.³²⁵

TABLE 17.3 Some Enterovirus 71 Outbreaks, 1969–2009

Year	Location	Clinical findings
1969–1973	California	Aseptic meningitis, encephalitis
1972	New York	Aseptic meningitis, encephalitis, hand-foot-and-mouth disease
1972	Australia	Aseptic meningitis, rash, polyneuritis, acute respiratory infection
1973	Sweden	Aseptic meningitis, hand-foot-and-mouth disease
1973	Japan	Hand-foot-and-mouth disease, aseptic meningitis
1975	Bulgaria	Aseptic meningitis, encephalitis, acute myocarditis, acute flaccid paralysis
1978 ^a	Hungary	Aseptic meningitis, encephalitis, acute flaccid paralysis
1985	Hong Kong	Monoplegia
1986	Australia	Central nervous system involvement
1987	United States	Acute flaccid paralysis, meningitis, encephalitis
1989	China	Hand-foot-and-mouth disease
1997	Malaysia	Fatal encephalitis, acute flaccid paralysis, hand-foot-and-mouth disease
1998	Taiwan	Fatal encephalitis, hand-foot-and-mouth disease
2000–2001	Australia	Severe neurologic disease, pulmonary edema
2005–2009	Viet Nam	Severe neurologic disease, hand-foot-and-mouth disease
2006	Brunei Darussalam	Severe neurologic disease, hand-foot-and-mouth disease, herpangina
2007–2009	China	Fatal encephalitis, hand-foot-and-mouth disease

^aA mixed epidemic of tick-borne encephalitis (chiefly in adults) and enterovirus 71 disease (chiefly in children).

Adapted from Melnick JL. Enteroviruses: polioviruses, coxsackieviruses, echoviruses, and newer enteroviruses. In: Fields BN, Knipe DM, Howley PM, eds. *Fields Virology*. 3rd ed. Philadelphia: Lippincott-Raven, 1996:655–712; with additional data from World Health Organization. *A Guide to Clinical Management and Public Health Response for Hand, Foot and Mouth Disease (HFMD)*. Geneva: World Health Organization, 2011.

Paradoxically, poliomyelitis and possibly other EV diseases tend to be *diseases of development*. In the case of poliomyelitis, improvement in a country's hygienic and socioeconomic conditions (before vaccination programs) successfully reduces the incidence of paralysis caused by PV and leads to a transitional period in which there is a delay in age of first infection with a subsequent temporary increase in the paralysis-to-infection ratio. Before the introduction of the PV vaccine in the United States and other developed countries, paralytic poliomyelitis was disproportionately a disease of the middle and upper socioeconomic classes; this disease distribution was a result of infection at an older age, when paralysis was a more frequent

complication. Ironically, the delay was a result of improved hygiene. The infant mortality rate, a general indicator of a country's level of health development, may be inversely correlated with the age-specific incidence of poliomyelitis.²⁷⁴

Enterovirus diseases, and possibly also EV infections, occur more frequently in males than in females,^{132,287} although some exceptions have been described.⁹⁴ In numerous reports, the male-to-female ratio appears generally to range between about 1.2 and 2.5:1; that is, approximately 55% to 70% of such diseases occur in males. Male predominance tends to be greater for the more severe diseases (e.g., CNS disease or carditis) than for less-severe disease (e.g., pleurodynia, hand-foot-and-mouth disease, respiratory disease, acute hemorrhagic conjunctivitis, rash, or undifferentiated febrile illness).

The apparent predominance of enteroviral infections among males may have both sociologic and biological explanations. Population-based measurements of infection (e.g., serosurveys), which should be gender neutral, have not consistently demonstrated a higher infection rate for males. Several additional explanations for the male predominance have been proposed on the basis of studies of infections in healthy children:¹²³ a longer duration of virus excretion occurs in males than in females (leading to increased chance of identifying infected males); and a higher virus titer occurs in the feces of males (leading to a similar increase in diagnosis). Another possibility is that, indeed, more frequent infections occur in males because of a greater exposure to the pathogen, perhaps because of differences in the parental treatment and play habits of younger boys and greater activity among older boys. An additional possibility is that males are more likely to develop a serious illness from a given EV infection than females. For example, the reason that human myopericarditis is more common in adolescent and adult males than in females (except in pregnant and postpartum women)⁴²³ could be caused by sex-related endocrine effects leading to differences in disease susceptibility.

Transmission

Enteroviruses can be isolated from both the lower and upper alimentary tract and can be transmitted by both fecal–oral and respiratory routes. Fecal–oral transmission may predominate in areas with poor sanitary conditions, whereas respiratory transmission may be important in more developed areas.¹⁶⁹ The relative importance of the different modes of transmission probably varies with the particular EV and environmental setting. It is believed that almost all EVs, except possibly EV70, can be transmitted by the fecal–oral route; however, it is not known whether most can also be transmitted by the respiratory route. EV70 and CVA24 variant, the agents that cause acute hemorrhagic conjunctivitis, are seldom isolated from the respiratory tract or stool specimens and are probably primarily spread by direct or indirect contact with eye secretions.²³⁶ Enteroviruses that cause a vesicular exanthem presumably can be spread by direct or indirect contact with vesicular fluid, which contains infectious virus.

It is likely that EVs are transmitted in the same manner as are other viruses causing the common cold—that is, by hand contact with secretions (e.g., on the hand of another person) and autoinoculation to the mouth, nose, or eyes. Direct bloodstream inoculation, usually by laboratory accidents (e.g., needlesticks) can result in EV infection; however, neither blood transfusion nor mosquito or other insect bite appears to be a

significant route of transmission. The isolation of EV from flies has led to a suspicion that houseflies (*Musca domestica*) and various filth flies may be vehicles of mechanical transmission. No evidence indicates that venereal transmission is important.

Transmission within households has been well studied for both PV and nonpolio EV. Small children generally introduce EV into the family, although young adults make up the majority of index cases in some outbreaks of acute hemorrhagic conjunctivitis.³⁶⁶ Intrafamily transmission can be rapid and relatively complete, depending on duration of virus excretion, household size, number of siblings, socioeconomic status, immune status of household members, and other risk factors.¹⁴⁵ Transmission has been generally found to be greatest in large families of lower socioeconomic status with a greater number of children 5 to 9 years of age and with no evidence of serologic immunity to the virus type. Not surprisingly, infections in different family members can result in different clinical manifestations.

Observations of household transmission of various EVs have documented that many infected contacts do not become ill and that the extent of secondary transmission varies with different EVs. Household secondary attack rates in susceptible members may be greatest for the agents of acute hemorrhagic conjunctivitis (EV70 and CVA24 variant) and for PV, and of lesser magnitude for the coxsackieviruses and echoviruses. In some studies, secondary attack rates may be 90% or greater, although they are typically lower. New York Virus Watch data indicate that EV infections were more frequent among children 2 to 9 years of age and that secondary CV infections were more frequent in mothers (78%) than in fathers (47%).²³¹ In the same study, coxsackieviruses spread to 76% of exposed susceptible persons versus 25% of exposed persons who had detectable antibody to the infecting type; echoviruses infected 43% of those who were susceptible and only one person with antibody. The greater spread of polioviruses and coxsackieviruses may derive from longer periods of virus excretion.

Transmission occurs within the neighborhood and community, particularly where people congregate. In addition, as with many other viruses, EV can be rapidly transmitted within institutions when circumstances permit (e.g., crowding, poor hygiene, or contaminated water). School teams or activity groups and institutionalized ambulatory retarded children or adults may be at special risk.¹¹ Despite crowding, EV transmission is not usually accelerated to a noticeable degree in institutions where good sanitation is found.

As a result of widespread but incomplete PV immunization, rare PV-susceptible enclaves have arisen. These usually consist of unvaccinated religious groups in countries with an otherwise high prevalence of PV immunity. Despite the barrier of millions of immune persons, PV outbreaks have occurred in some of these enclaves.³²⁴ The frequency and ease of international travel may result in the continuous introduction of wild-type PV in all regions of the world, indicating that a large proportion of the population must be vaccinated if poliomyelitis epidemics are to be prevented. This suggests that herd immunity may be of only limited value in protecting groups of susceptible persons who have regular contact with outside populations, and it raises questions about the risks that such groups may pose to the community at large.

Nosocomial transmission of various CVA and B and the echoviruses has also been well documented, typically in newborn

nurseries. Hospital staff may have been involved in mediating transmission in some of these outbreaks. EV70, as well as CVA24 variant, is highly transmissible and can cause outbreaks in ophthalmology clinics when instruments are inadequately cleaned between patients. An apparent outbreak of CVA1, which included some fatal cases, has been reported in bone marrow transplant recipients.³⁹⁴

Although human EVs have been isolated from various environmental sources, humans are thought to make up the only important natural reservoir.^{101,110} Survival beyond a few weeks does not generally occur, although EV can survive for months in favorable environmental conditions; these favorable conditions include neutral pH, moisture, and low temperatures, especially in the presence of organic matter, which protects against inactivation. Simian enteroviruses have been identified that are closely related to a number of human viruses,^{149,305,307,315,334} and human enteroviruses have been detected in free-living nonhuman primates,³⁰⁸ but it is not known whether primates can serve as a reservoir for human infection.

Although little evidence suggests that EVs found in the environment are of public health importance, concern has been expressed about possible dangers of contaminated sources of water (Fig. 17.7). Recreational swimming water has been investigated in several studies, and EVs have been isolated from swimming and wading pools in the absence of fecal coliforms and in the presence of *recommended* levels of free residual chlo-

rine. CVB5 was isolated from an unchlorinated lake swimming area during an outbreak at a boys' camp in Vermont, although the outbreak itself was explained by person-to-person transmission. In one study, the relative risk of EV infection among children was found to be significantly higher for beach swimmers, especially for those younger than 4 years of age.⁸⁴ These reports suggest that swallowing of contaminated pool or lake water may theoretically account for transmission, but no proof exists that this type of transmission is significant in recreational settings.

Enteroviruses have been found in surface and ground waters throughout the world. In the tropics, virus survival is more prolonged in ground water because it is cooler than surface water. As in the case with swimming pools, EV can be found in these waters even after chlorination and even in the absence of fecal coliforms. In industrialized countries, EV transmission from potable water is apparently uncommon but is a constant source of concern for public health investigators, because the usual conditions under which city drinking water is chlorinated may be insufficient to completely inactivate enteroviruses.

Enteroviruses have been isolated from raw or partly cooked mollusks and crustacea and their overlying waters.¹³⁴ Shellfish rapidly concentrate many viruses, including EV. These viruses can survive in oysters for 3 weeks at temperatures of 1°C to 21°C. To date, no outbreak of EV disease has been attributed to consumption of shellfish. Other food-borne transmission

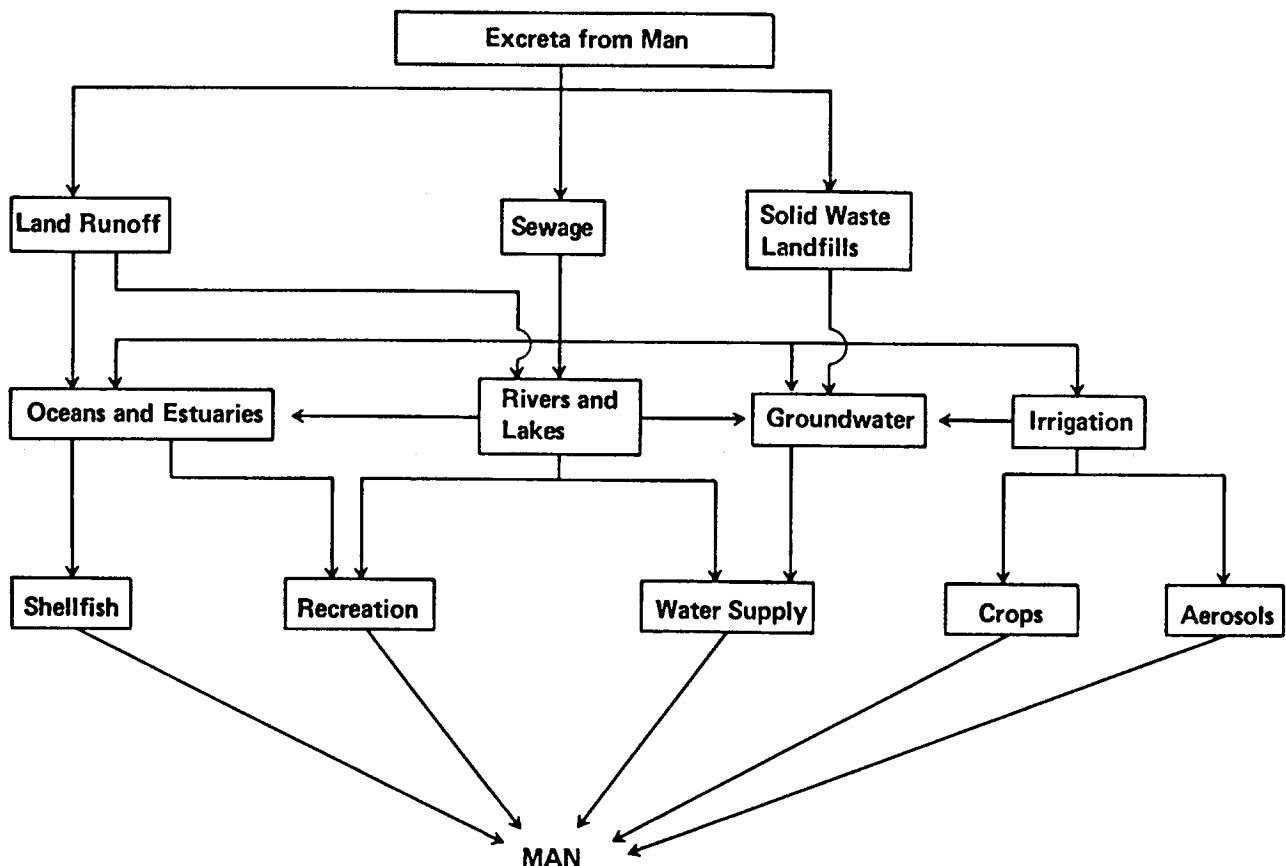

FIGURE 17.7. Routes of potential enteric virus transmission in the environment. (From Melnick JL. Current status of poliovirus infections. *Clin Microbiol Rev* 1996;9[3]:293–300, with permission.)

has been documented but is thought to be uncommon. A 1976 outbreak of aseptic meningitis attributed to echovirus type 4 was apparently caused by consumption of contaminated coleslaw at a large picnic (Centers for Disease Control and Prevention, unpublished data, 1976).

Enteroviruses, especially polioviruses, are regularly found in sewage. Enteroviruses are more prevalent in sewage from areas with low socioeconomic conditions or with large proportions of young children. In addition, sewage workers have been shown to have a higher prevalence of serum antibodies to EV than highway maintenance workers, which is consistent with an occupational risk.⁷⁴

Soil and crops also provide conditions favorable to EV. Enteroviruses survive well in sludge and remain on the surface of sludge-treated soil and even on crops. Air samples from aerosolized spray irrigants using contaminated effluents have also been found to contain EV.²⁸⁵ Survival of EV on vegetable food crops exposed to contaminated water or fertilizer has not been proved to be associated with virus transmission.

Prevalence and Disease Incidence

Incidence data about diseases caused by particular EV types can be derived from prospective longitudinal surveillance of a defined population or from a sample of the population in which the occurrence of disease or infection can be reliably determined. The Virus Watch program in the 1960s in U.S. cities exemplifies this type of surveillance study, in which specimens from subject children were obtained every 2 weeks for virologic evaluation.^{80,231,382} Although difficult and extremely expensive, such prospective cohort studies avoid many of the pitfalls of passive surveillance, and they allow interpretations about both infection and disease incidence.

Less-useful information is based on passive case finding. Ascertainment may be incomplete because the surveillance system is likely to identify a case only if it is easily recognizable and diagnosed by someone who decides to report it. Because such data indicate neither how many ill persons were not reported nor how many ill persons had negative laboratory tests, the information is mostly of qualitative value; however, it may be useful in indicating trends. Despite these limitations, occasional reports do appear.^{29,221}

In the United States, EV surveillance data are collected and analyzed by the Centers for Disease Control and Prevention (CDC). The data have been reported irregularly since the beginning of the program in 1961.^{221,286,288} In the United States, the only notifiable enteroviral diseases are poliomyelitis and encephalitis. These are reportable by diagnosis only (e.g., encephalitis) and not etiology (e.g., echovirus encephalitis). Such disease-based surveillance is the most accessible but least representative of all surveillance data.

Enterovirus excretion does not necessarily imply association with disease, because most such excretion is asymptomatic. This applies particularly to developing countries where EVs are ubiquitous and childhood infections commonplace and characteristically silent.

Enterovirus activity in populations can be either sporadic or epidemic, and certain EV types are associated with both sporadic and epidemic disease occurrences. The reported incidence or prevalence of a given EV disease may actually or artifactually be increased in an outbreak situation when sudden focus of attention improves diagnosis and reporting of cases,

but this may also increase reporting of *noncases*. In addition, there may be a tendency for other strains to be excluded when a particular strain is predominant in a community; however, large communities with summer enteroviral disease typically support co-circulation of several different types simultaneously and in no particular pattern.

An important concept in understanding the epidemiology of the EVs is variation: by serotype, by time, by geographic location, and by disease. This concept is illustrated in surveillance studies of nonpolio EV infections. For example, Figure 17.8 summarizes the data for the years 1970–1998 for CVB3, echovirus 11, and echovirus 30 isolates in the United States collected and analyzed by the CDC. These data illustrate endemic and epidemic patterns of EV prevalence. The epidemic pattern, as typified by E11 and E30, is characterized by peaks in numbers of isolations followed by periods with few

FIGURE 17.8. Reported enterovirus isolations in the United States, 1970–1998. The graphs represent the percentage of total enterovirus isolations in a given year for each of three common serotypes, coxsackievirus B3 (CB3), echovirus 11 (E11), and echovirus 30 (E30). Note that full scale for the coxsackievirus B3 panel is 20%, whereas it is 50% for both of the echoviruses.

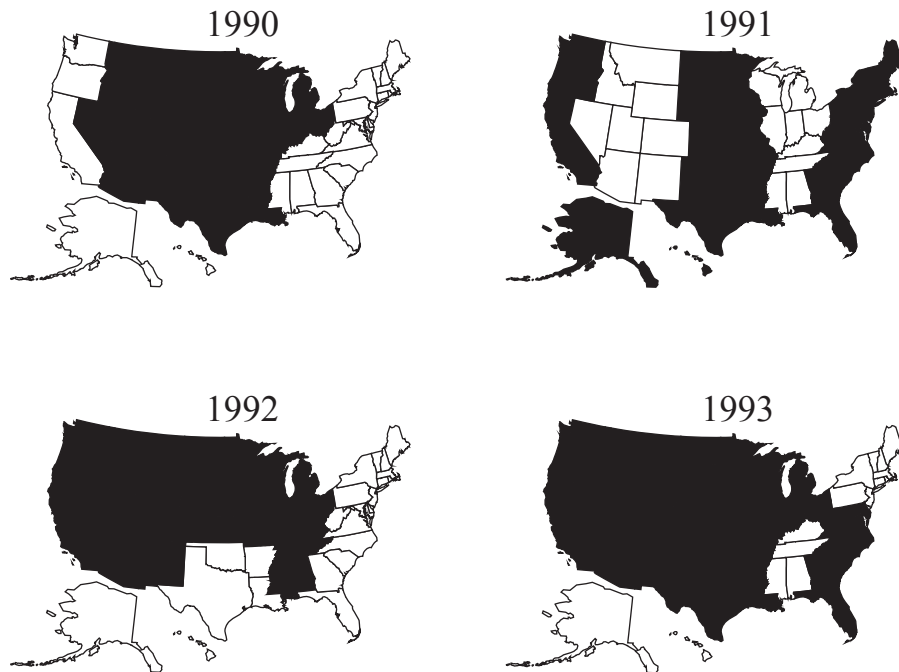

FIGURE 17.9. Geographic distribution of echovirus 30 isolates in the United States, 1990–1993. Maps represent regions of the United States where echovirus 30 was one of the three most common enterovirus isolates for the given year. States are shaded on a regional basis, because not all states report enterovirus isolation data.

isolations.²²¹ These peaks may be sharp (1- or 2-year) or broad (multiyear) periods of increased virus isolations. For example, during the study period, several major epidemics occurred of echovirus 30 in the United States: outbreaks from 1981 to 1982, 1990 to 1994, and 1997 to 1998. By contrast, endemic viruses (e.g., CVB3) are isolated nearly every year and in similar numbers each year. Even with endemic viruses, larger outbreaks do occasionally occur, as with CVB3 in 1980. Similar endemic and epidemic patterns are seen for the other echoviruses and coxsackie A viruses.

Variation by location is also a major characteristic of EV. Outbreaks can be restricted to small groups (e.g., schools and day care centers) or to select communities, or they may become widespread at the regional, national, or even international level. Outbreaks in small groups can sometimes be linked epidemiologically to a breakdown in hygiene practices. Even during national outbreaks of a specific serotype, the location of virus activity may not be uniform. During the period 1990–1993, echovirus 30 was the most commonly isolated EV in the United States (Fig. 17.9). As can be seen in the figure, not all parts of the country had echovirus 30 isolates during the entire period. Some areas, such as the New England states, had extensive circulation in only 1 year, whereas other areas, such as the entire western United States, had extensive virus circulation for 3 or more of the 4 years. It is important to note, therefore, that aggregate national data can obscure significant regional and local variation in viral prevalence.

In temperate climates, EVs are characteristically found during the summer and early autumn, although outbreaks can continue into the winter. In fact, naturally occurring EVs have a distinct seasonal pattern of circulation that varies by geographic area; in contrast, live attenuated PV (mostly vaccine strains) are isolated year round, reflecting the routine administration of poliomyelitis vaccine to children. In tropical and semitropical areas, circulation tends to be year-round or associated with

the rainy season. In the United States, 23 years of surveillance indicated that 78% of EV isolations were made during the five summer or fall months of June to October.²²¹ In a 6-year study of viral CNS disease, 85% of enteroviral disease, compared with 12% to 26% of diseases caused by other viral agents, occurred between June and November.²⁸⁶

Many studies have examined the prevalence of antibodies to the EVs in specific populations, as has been reviewed elsewhere,^{273,284} with several important conclusions. First, the number of persons who have neutralizing antibody to any given EV is large, indicating a high incidence of past infection. A high incidence of recent infection is also suggested by surveys of IgM antibodies to EV, which typically show 4% to 6% positivity. Second, infections with one serotype of EV can boost antibody titers to other EV serotypes as measured by either IgM or neutralization. The pattern of the heterotypic response varies by serotype and among individuals. The nature of this heterotypic response has been explored through the identification of specific epitopes using monoclonal antibodies and peptide antisera.^{141,362,433} Third, the pattern of antibody prevalence by serotype varies by geographic location, time, and age. Thus, prevalence data from different years and locations are not directly comparable. These three points must be considered when interpreting the findings of serologic studies of associations between EV infection and disease.

Molecular Epidemiology

Study of the molecular variation of viral proteins or nucleic acid may contribute significant epidemiologic information on viral diseases (see Diagnosis). Molecular epidemiologic studies have helped in our understanding of EVs including the following: providing the opportunity for unequivocal strain identification, providing insights into EV classification and taxonomy, clarifying the origins of outbreaks, and allowing identification of strains transmitted between outbreaks. For the EVs, and in

particular PV, the primary method used to generate epidemiologic information is direct analysis of genomic variation using nucleic acid sequencing. Previously, both monoclonal antibodies and oligonucleotide fingerprinting were also used to study variation in PV and EV; however, these approaches are limited by their ability to show similarities and small differences only among relatively closely related viruses. Neither technique, however, is able to readily detect any patterns among seemingly unrelated virus isolates. The introduction of the technique of genomic nucleic acid sequencing and its application to the study of wild PV isolates from different parts of the world has significantly extended the epidemiologic power of molecular studies.³⁴⁸ By analyzing the random mutations that occur in the genome of different PVs, closely related viruses were easily detected, and, in addition, more distantly related viruses were clustered into distinct geographic groupings of endemic circulation. This approach allowed epidemiologic links to be extended beyond those identified with other techniques.

Nucleic acid sequencing technology has been most comprehensively applied to studies of PV, where the information has proved valuable for supporting the global PV eradication program.^{215–217} From these studies, it is possible to determine (a) if an isolated PV is related to vaccine virus, (b) similarities among isolates in an epidemic, and (c) differences among isolates from different geographic areas. By comparing the changes that are observed between virus strains, the geographic and temporal origin of a virus can be determined. Building on a nucleic acid sequence database of PV strains worldwide, it has been possible to develop rapid approaches to tracking wild PV strains.^{9,254,294,348,450}

Studies on the molecular epidemiology of nonpolio EV have focused on the evolutionary inference derived from the comparison of virus isolates within a serotype over time, as well as the comparison of isolates from different serotypes and even between different genera within the *Picornaviridae*. Molecular

epidemiologic studies using sequencing have been reported for CVB1, CVB5, echovirus 30, and EV71.^{47,102,237,310,452} One of the studies of CVB5 isolates examined the pattern of genetic changes over three separate outbreaks in the United States. The nucleotide sequence from multiple isolates from the epidemics showed that each of the epidemics was caused by a single genotype. The genotype of CVB5 observed in the 1967 epidemic showed more similarity to the virus observed in the 1983 epidemic than to viruses isolated during the intervening years,²³⁷ suggesting discontinuous transmission of epidemic CVB5 in the United States during this time. In an analogous manner, echovirus 30 genotypes have demonstrated an overlapping succession among the isolates characterized in the United States.³¹⁰ More than one genotype may be found in certain periods, and the displaced genotype can be found in other parts of the world after isolations have ceased in the United States for many years. In studies of EV71 isolates, three distinct genotypes have been characterized.⁴⁷ Unlike the situation with echovirus 30 and more similar to the CVB5 example, the transition from one genotype to another occurred during a single year, 1987, and the older genotype has not been isolated since in the United States despite isolation in other parts of the world.

CLINICAL FEATURES

Most EV infections are asymptomatic. On the other hand, these viruses can cause a spectrum of clinically distinct syndromes when they lead to disease. Tables 17.4 through 17.7 list the prototype EV strains and the illness, if any, in the person from whom the prototype virus was isolated. Individual serotypes generally lead to varied symptomatology and disease processes. Similarly, individual clinical disorders can generally be caused by a number of different EVs. On occasion, however, particular syndromes are associated with specific EVs

^aEchovirus types 1 and 8 share antigens, type 1 having the broader spectrum. Type 10 was soon excluded from this group: it turned out to be a larger RNA virus and was reclassified as a prototypic reovirus. Type 28 was reclassified as rhinovirus type 1. Types 22 and 23 have been reclassified as members of the genus *Parechovirus* and are named parechovirus 1 and 2; these viruses along with Ljungan virus represent the only members of this new genus. Type 34, DN-19, is now considered a prime strain of CV A24, rather than a distinct echovirus. Additional newer serotypes (EV73 and higher) are proposed new types defined on the basis of genetic sequence information.

(Table 17.8). For example, acute hemorrhagic conjunctivitis is usually caused by the CVA24 variant or EV70. Acute flaccid paralysis is usually caused by PV or EV71. The occasional isolates from cases of diabetes are usually CVB serotypes.

Poliomyelitis

As is true for nonpolio EV, infection of most patients with PV does not result in disease or lead to any symptomatology. The most common symptomatic disease caused by PV, known as *abortive poliomyelitis*, is a mild febrile illness with or without gastrointestinal signs that occurs in 4% to 8% of individuals. The incubation period from infection to the onset of abortive poliomyelitis is usually 1 to 3 days, although symptoms can be seen as late as 5 days after infection. Less frequently, PV infection results in aseptic meningitis. This nonparalytic illness has the typical features of viral meningitis, with fever, headache, and meningeal signs but an absence of signs of CNS parenchymal involvement. The meningitis has a self-limited course and lasts for a few days to 2 weeks.

On average, only about 1 in 200 PV infections in a fully susceptible population results in the paralytic disease known as *poliomyelitis*. The incubation period from infection to the onset of paralysis is usually 4 to 10 days, although it can be as short as 3 days or longer than a month. The paralysis generally occurs 2 to 5 days after headaches occur and peaks within a few days. Usually, a prodrome occurs with sensory complaints and shooting or aching pains in muscle. The muscle pains may reflect growth of the virus in this tissue, which is known to occur.²⁷⁰ In children can be seen a biphasic or *dromedary* course of neurologic involvement, and paralysis can occur as the initial symptom.

Paralysis is classified as either spinal or bulbar, depending on whether the spinal cord or brainstem, respectively, is involved. Not infrequently, the spinal form becomes associated with the bulbar form during the course of the disease, resulting in so-called *bulbospinal polio*. Spinal polio is usually asymmetric, flaccid, and limited to the extremities and trunk and varies from mild weakness to quadriplegia. Only about 10% to 15%

TABLE 17.7 Enterovirus Species D (EV-D)

Type	Prototype strain	Geographic origin	Illness in person with prototype	Accession number
EV68	Fermon	California	Lower respiratory illness	AY426531

EV111	KK2640	Cameroon	None ^a	JF416935

^aThe prototype strain was detected in a chimpanzee, but another strain of EV111 was detected in a human with acute flaccid paralysis in the Democratic Republic of the Congo.

TABLE 17.8 Clinical Syndromes Associated with Infections by Enteroviruses

Polioviruses, types 1–3
Paralysis (complete to slight muscle weakness)
Aseptic meningitis
Undifferentiated febrile illness, particularly during the summer
Coxsackieviruses, group A, types 1–24
Herpangina
Acute lymphatic or nodular pharyngitis
Aseptic meningitis
Paralysis
Exanthema
Hand-foot-and-mouth disease (A10, A16)
Pneumonitis of infants
“Common cold”
Hepatitis
Infantile diarrhea
Acute hemorrhagic conjunctivitis (type A24 variant)
Coxsackieviruses, group B, types 1–6
Pleurodynia
Aseptic meningitis
Paralysis (infrequently)
Severe systemic infection in infants, meningoencephalitis, and myocarditis
Pericarditis, myocarditis
Upper respiratory illness and pneumonia
Rash
Hepatitis
Undifferentiated febrile illness
Echoviruses, types 1–33
Aseptic meningitis
Paralysis
Encephalitis, ataxia, or Guillain-Barré syndrome
Exanthema
Respiratory disease
Others: Diarrhea
Pericarditis and myocarditis
Hepatic disturbance
Enterovirus, types 68–116 ^a
Pneumonia and bronchiolitis
Acute hemorrhagic conjunctivitis (type 70)
Paralysis (types 70, 71) ^b
Meningoencephalitis (types 70, 71)
Hand-foot-and-mouth disease (type 71)

^aSince 1969, new enterovirus types have been assigned enterovirus type numbers rather than being subclassified as coxsackieviruses or echoviruses. The vernacular names of the previously identified enteroviruses have been retained.

^bNumerous additional types have been identified in stool from acute flaccid paralysis cases, but an etiologic link has not been confirmed.

Adapted from Melnick JL. Enteroviruses: polioviruses, coxsackieviruses, echoviruses, and newer enteroviruses. In: Fields BN, Knipe DM, Howley PM, eds. *Fields Virology*. 3rd ed. Philadelphia: Lippincott-Raven, 1996:655–712.

of poliomyelitis cases are bulbar, a term indicating involvement of the motor cranial nerves or medullary centers controlling respiration and the vasomotor system. Cranial nerves IX and X, those most affected, lead to paralysis of the pharyngeal and laryngeal muscles with resultant difficulty swallowing and talking. Involvement of other cranial nerves can lead to

weakness of the face (VII) and tongue (XII). Most dreaded is involvement of the brainstem reticular formation, resulting in respiratory compromise, potentially requiring ventilatory support. Also seen is autonomic involvement, which manifests as abnormalities of sweating, urination, defecation, and blood pressure control. Recovery can be delayed significantly. Not infrequently, one extremity is left severely weak and atrophic, with a relatively normal contralateral limb.

The pathology of poliomyelitis is one of inflammation and destruction of the gray matter of the CNS, especially of the spinal cord. Motor neurons up and down the neuraxis can be infected, including upper motor neurons located rostrally in the brainstem and cerebral hemispheres in addition to the anterior horn lower motor neurons in the spinal cord. The widespread nature of the gray matter infection demonstrates that the disease is frequently a polioencephalomyelitis (i.e., inflammation of the gray matter of the brain and spinal cord) rather than merely a poliomyelitis (inflammation of the gray matter of the spinal cord). Interestingly, perivascular mononuclear inflammatory cells can persist for months, although virus is difficult to culture from the spinal cord after a week.³⁷ Although the focus of pathology in the spinal cord is in the anterior horn, abnormalities also occur outside the motor system in the posterior horn and intermediolateral column. Similarly, the brainstem shows involvement of a number of sensory cranial nerve nuclei and of the reticular formation in addition to the motor cranial nerve nuclei. Neurons die with evidence of chromatolysis followed by neuronophagia. Recent investigations of CD155 transgenic mice have reported that spinal cord neurons die by apoptosis.¹²⁵

Poliomyelitis or acute flaccid paralysis can occur as a result of infection with other EVs besides PV. EV71 is emerging as the most important virulent neurotropic EV during the poliomyelitis eradication period. This virus causes epidemics of poliomyelitis-type disease, including bulbar disease.⁷² In an EV71 epidemic in Bulgaria in 1975, a paralytic disease occurred in as many as 21% of approximately 700 patients, with a case fatality rate approaching 30%.³⁷³ EV71 is also associated with epidemic encephalitis and meningitis (see Clinical Features: Meningitis and Encephalitis). EV70, a cause of epidemics of acute hemorrhagic conjunctivitis, can lead to a severe and acute paralytic disease.⁴¹¹ The incidence of paralysis is probably 1 of 10,000 infections.¹⁹⁷ These patients can also have cranial nerve palsies, autonomic abnormalities, and sensory signs. Sometimes, EV70 infections cause isolated cranial nerve palsies, most commonly involving the facial nerve. The eye disease is usually spread by direct or indirect contamination of the eye rather than the fecal–oral route. Some echoviruses and coxsackieviruses have also been associated with acute flaccid paralysis (e.g., CVA7 virus).¹³⁷

Postpolio Syndrome and Amyotrophic Lateral Sclerosis

Patients with postpolio syndrome complain of new weakness, fatigue, and pain decades after paralytic poliomyelitis. One subgroup of this syndrome, called *postpoliomyelitis progressive muscular atrophy*, is an uncommon primary neurologic disorder manifested by slowly progressive atrophy of muscles with evidence of ongoing motor nerve damage.⁵⁴ Some investigators have reported a persistent PV infection in the spinal fluid or

CNS tissue from patients with postpoliomyelitis progressive muscular atrophy,^{248,249,290,333,371} but others have failed to confirm these findings.^{201,272,361} One of the groups that originally reported EV genome in patients with postpolio syndrome later claimed that both patients and controls had evidence of enteroviral genome in the CNS.²⁹¹ Although the PV genome of a mouse-adapted mutant PV has been reported to persist at low levels following experimental infection of mice,⁹⁷ the only consistent evidence for persistent PV infection in humans has been found in individuals who are immunocompromised. We await more convincing data demonstrating that a persistent infection underlies the postpolio syndrome.

The issue of whether PV can persist in postpoliomyelitis progressive muscular atrophy has raised questions about whether PV or another EV is involved in amyotrophic lateral sclerosis, a chronic progressive weakening disease of unknown cause associated with death of motor neurons. A possible role for EV in amyotrophic lateral sclerosis seems unlikely given the immunocompetence of these patients and the noninflammatory pathology of the disease. Although some studies have reported enteroviral genomic sequences in tissues of patients with amyotrophic lateral sclerosis and motor neuron diseases, a recent investigation failed to find evidence to support this.³⁰⁴

Meningitis and Encephalitis

Aseptic meningitis is a nonbacterial inflammation of the meninges associated with fever, headache, photophobia, and meningeal signs in the absence of signs of brain parenchymal involvement.³⁵⁸ The syndrome is the most common CNS infection, with 7,000 cases of aseptic meningitis reported per year in the United States and an actual incidence believed to be 10-fold higher.³⁵⁷

Enteroviruses are the main recognized cause of aseptic meningitis in both children and adults in developed countries. Enteroviruses were identified in 85% to 95% of cases in which a specific pathogen was cultured.³⁵⁸ In one study, 62% of infants younger than 3 months of age with aseptic meningitis had CVB as the etiologic agent.²⁰⁹ Of note, aseptic meningitis is the most common clinical syndrome caused by EV that results in medical attention.

Enteroviruses should be suspected as the causative agent for aseptic meningitis occurring in the summer and fall in temperate zones. The seasonal increase in incidence of enteroviral aseptic meningitis may result because the fecal–oral route of transmission is facilitated in warm periods when less clothing is worn.¹⁹⁷ Fever is common in patients with EV-induced aseptic meningitis, as with most cases of aseptic meningitis. At times, the fever has a biphasic pattern, initially associated with constitutional symptoms and then returning with meningeal signs. One may see nonneurologic abnormalities associated with enteroviral meningitis (e.g., rash), which may be helpful in the diagnosis and identification of the particular enteroviral serotype.¹⁹⁷ For example, rashes have been associated with CNS disease caused by CVA5, A9, and A16 and echoviruses 4, 6, 9, and 16. The rash associated with echovirus 9 meningitis can be petechial, resembling that seen with meningococcemia.

Encephalitis signifies that the brain parenchyma is infected and is not infrequently associated with a disturbed state of consciousness, focal neurologic signs, and seizures. The distinction between aseptic meningitis and encephalitis is important because the absence of parenchymal involvement in aseptic

meningitis suggests a more benign condition and more favorable prognosis. Encephalitis is usually associated with aseptic meningitis, usually resulting in a meningoencephalitis.

Although a specific virus is not usually identified in most cases of encephalitis, and although the number of cases in which an EV has been identified as the cause of encephalitis is low, EVs nevertheless rank second to herpes simplex virus and comparable to arboviruses as a recognized cause of encephalitis in the United States. The New York State Department of Health found evidence of EV genome by PCR in the spinal fluid of 3 of 41 cases of encephalitis over the period from July 1997 to November 1998;¹⁷² herpes simplex virus genome and arbovirus genome were each found in 5 cases.

Patients with EV encephalitis usually have a global neurologic depression in function, although occasionally seen are focal neurologic signs, resembling herpes simplex virus encephalitis.²⁸³ Cases associated with an acute cerebellar ataxia have been reported in children infected with various EVs, including PV, echoviruses 6 and 9, and coxsackieviruses A2 and A9.¹⁹⁷ Other uncommon clinical manifestations reported include acute hemiplegia, opsoclonus-myoclonus, movement disorders, and Guillain-Barré syndrome.¹⁹⁷

The meningeal syndrome is usually self-limited and benign, with evidence of improvement in days to a week. Deaths have been reported, however, following infection with a number of enteroviruses, including CVB1 and echoviruses 9, 17, and 21.¹⁹⁷ Morbidity and mortality are also increased in the neonate. The neonate's disease tends to be especially severe when the disease appears soon after birth, perhaps reflecting perinatal spread of virus to the fetus from the mother. Mortality is increased in the neonate partly because the aseptic meningitis can be associated with systemic disease (e.g., hepatitis and myocarditis) as well as encephalitis. The largest study of recovered patients failed to find any neurodevelopmental abnormalities above levels seen in controls.³⁵²

Isolation of EV may be unsuccessful because a particular EV may grow poorly in cell culture or because inhibitory factors (e.g., neutralizing antibody) may be present in the spinal fluid. With the use of reverse transcriptase (RT)-PCR, EV genome may be found in a significant number of culture-negative spinal fluid samples from cases of aseptic meningitis. The potential usefulness of RT-PCR can be seen in a report of a Swiss epidemic of aseptic meningitis caused by echovirus 30, when the EV genome was identified using this technique in 42 of 50 spinal fluid cultures (84%) that were negative for virus isolation.¹³³ On the other hand, the use of RT-PCR may be unsuccessful because some so-called generic RT-PCR primers may fail to hybridize well to particular EVs because of a difference in target sequence.

In some areas of the world, epidemics of EV71^{72,373} have been associated with a high incidence of aseptic meningitis as well as CNS parenchymal involvement; the CNS infection has caused acute flaccid paralysis as well as a more varied clinical symptomatology.²⁷⁴ As noted, EV71 is emerging as the most significant neurotropic EV in some areas of the world. This virus circulates in the United States, and 26% of adults tested in a seroepidemiologic study in New York in 1972 had antibody.⁹⁵ An epidemic of EV71 infection in 1998 in Taiwan caused frequent CNS disease and more than 100,000 reports of hand-foot-and-mouth disease or herpangina (see Respiratory Infections, Herpangina, and Hand-Foot-and-Mouth

Disease), which may correspond to 1 million actual cases of EV infection.¹⁶¹ The patients with hand-foot-and-mouth disease had vesicular lesions on their hands, feet, mouth, and, at times, buttocks, whereas the patients with herpangina had vesicular lesions of the palate and pharynx. Of special concern was the finding of 405 severe cases with associated complications, 78 of which were fatal. Among the more severe cases, the case fatality rate in different areas ranged from 7.7% to 31.0%. Most of the hospitalized cases (80%) and the deaths (91%) were in children younger than 5 years of age. The most frequent complication was encephalitis. Other serious complications, which were associated at times with encephalitis, included aseptic meningitis, myocarditis, and pulmonary edema and hemorrhage. It is unclear whether the pulmonary signs were related to viral invasion of the lungs or to brain injury from the viral encephalitis.

A review¹⁷² of 41 hospitalized children with neurologic complications and culture-confirmed EV71 infection during the Taiwan epidemic in 1998 demonstrated an unusual and rather distinctive neurologic manifestation, brainstem encephalitis or rhombencephalitis. The mean age of the 41 children was 2.5 years (with a range from 3 months to 8.2 years). There was frequently an associated condition: hand-foot-and-mouth disease in 68%, or herpangina in 15%. The neurologic disease usually followed the initial illness of fever and skin or mucosal lesions, and it was manifested as rhombencephalitis (37 patients), aseptic meningitis (3 patients), and acute flaccid paralysis (associated with the disease in 4 patients, and following rhombencephalitis in 3 of the 4). At times, breathing difficulties and coma were seen in the patients with rhombencephalitis, progressing to death in five. The brainstem and spinal cord pathology was presumably related to direct viral injury, because virus was cultured from the spinal cord and brainstem of the one patient who underwent autopsy. Five of the patients who survived had neurologic sequelae. EV71 brainstem involvement was also seen during an epidemic in Malaysia in 1997, but not in earlier epidemics. In contrast, hand-foot-and-mouth disease and herpangina did not occur during the previous epidemics in Bulgaria and Hungary. It is not clear whether the changes in EV71 disease phenotype represent the emergence (or re-emergence) of a more virulent strain or whether it is related to the serologic status of the at-risk populations.

The presence of immunodeficiency predisposes to a syndrome of EV-induced aseptic meningitis or meningoencephalitis, at times producing a persistent CNS infection. McKinney et al.²⁷⁰ reviewed more than 40 cases of chronic enteroviral meningoencephalitis in patients with congenital immunodeficiencies, most commonly X-linked agammaglobulinemia. Clinical features were remarkably varied and included headaches, seizures, ataxia, a disturbed state of consciousness, motor deficits, personality changes with cognitive decline, and sensory disturbances. At times, patients had other associated abnormalities, such as dermatomyositis syndrome (in 21 of 41 patients; see Clinical Features: Muscle Disease), rashes (16 of 35 cases), edema (20 of 40 cases), and hepatitis (15 of 32 patients). Although some cases started abruptly, most tended to be slowly progressive, at times lasting years, and with a frequent fatal outcome. Most patients had a spinal fluid mononuclear cell pleocytosis with an increase in protein. Some cases at autopsy had evidence of inflammatory infiltrates in the heart, lungs, kidneys, adrenal glands, thyroid, and pancreas, in addition to the CNS.

Cardiac Disease

Myocarditis is an inflammation of the myocardium associated with damage that is unrelated to an ischemic injury. Myocarditis is frequently self-limited and subclinical, with few if any sequelae. On the other hand, the acute disease can lead to significant morbidity and even death. On the basis of well-established criteria, one study found evidence of myocarditis in approximately 1% of autopsies.¹³⁶

In some cases, myocardial inflammation may persist, producing a chronic myocarditis that can progress to dilated cardiomyopathy.^{61,205,354} In dilated cardiomyopathy, the heart is large, with impaired function and evidence of heart failure but with little or no inflammation. The incidence of dilated cardiomyopathy in the United States has been reported to be 6 per 100,000 cases,⁷⁷ with approximately 100,000 new cases each year. Because of the high mortality of dilated cardiomyopathy, patients are frequent recipients of heart transplants, making up perhaps 50% of all cardiac transplant patients. Of note is the observation that nonpolio EVs, especially CVB3, cause acute and chronic myocarditis in experimental animals, and that a contribution from the immune system to the chronic disease has been proposed (see Pathogenesis earlier).

Acute Cardiac Disease

CVB has long been considered one of the principal causes of viral myocarditis,⁸¹ and this view has been confirmed in several recent reports.^{16,106,262,264,266} Epidemiologic and other studies suggest that 70% of the general public will be exposed to cardiotropic viruses, and half of these individuals will develop acute viral myocarditis.³⁰⁶ It is believed that 1.5% of enteroviral infections, including 3.2% of CVB infections, result in overt cardiac signs or symptoms.¹³⁷ Myocarditis is a frequent autopsy finding in children who die of overwhelming CV infection.²⁰⁹ The peak age group in which myocarditis caused by CVB occurs is young adults, primarily between the ages of 20 and 39 years, with a higher prevalence among men.⁴²⁵

However, even the larger group of symptom-free individuals is at risk; collapse and death of young and vigorous individuals, especially during exertion, can result from catastrophic dysfunction of the electrical pathways in the heart, as a consequence of unsuspected acute viral myocarditis.^{31,415} A remarkably high prevalence of asymptomatic myocarditis has been shown by necropsy studies of victims of violent or accidental deaths; in this relatively random human population, approximately 1% had active myocarditis.¹³⁶

A summary of data from varied sources shows that the prevalence of enteroviral infection in acute myocarditis on the basis of serologic studies is 34% (214 positives in 636 patients) compared with 4% (44 of 1,139) of controls (199). However, these serologic studies demonstrating seroconversion with an EV do not prove that EV caused the cardiomyopathy, as they may result merely from an unrelated EV infection. In addition, evidence suggests that multiple EVs can circulate at the time of an epidemic, so that isolation of an EV does not prove its role in a disease; for example, more than 10 EVs were recovered from the community during an echovirus 9 epidemic.¹⁹⁷

A meta-analysis of data obtained from molecular studies (slot blot hybridization, *in situ* hybridization, and RT-PCR) published in 12 reports found 23% of cases (68 of 289) and 6% of controls (14 of 216) had evidence of EV genome in heart tissue, giving an odds ratio of 4.4 with a 95% confidence

interval of 2.4 to 8.2.²⁷ These data, coupled with reports of positive virus isolations from the heart, indicate that EV may represent a common cause of acute myocarditis. The surprisingly large number of positive findings in controls is presumed to result from difficulties in obtaining appropriately controlled heart tissue.

Chronic Cardiac Disease

Human DCM has multiple causes, both inherited and sporadic. A prior history of enteroviral infection of the heart, especially with CVB, has been implicated in sporadic human dilated cardiomyopathy.^{26,382} Although the majority of patients with symptoms recover well from acute myocarditis, the disease can have serious long-term sequelae; some 10% to 20% of people with symptoms (i.e., ~20,000 to 40,000 patients per year in the United States) will develop chronic disease, progressing over time to DCM.^{306,380} A summary of serologic data from multiple sources found that the prevalence of EV in dilated cardiomyopathy was 25% (64 of 260) compared to 10% of controls (26 of 255).²⁶⁸ These serologic data suffer from the same drawbacks that are noted earlier.

In contrast to acute myocarditis, no reports are found of isolation of EV from chronic dilated cardiomyopathy, suggesting that the virus may have a restricted expression or disappear following the acute infection; however, some reports exist of EV VP1 antigen in the heart of patients with dilated cardiomyopathy and chronic coronary disease.¹⁵

The difficulty in isolating infectious virus led to studies probing affected tissues for persistent enteroviral genome. A meta-analysis of data from molecular studies described in 17 published reports found 23% of the patients and 7% of controls had evidence of enteroviral genome, giving an odds ratio of 3.8 with a 95% confidence interval of 2.1 to 4.6.²⁷ The meta-analysis data are supportive of an association between EV infection and chronic cardiac disease; however, it remains a possibility that RNA from other laboratory-based enteroviral studies contaminated test samples in the highly sensitive PCR studies. Most of the hybridization and PCR studies did not include sequencing of the viral genome and, therefore, failed to prove more directly that an EV was involved. In a few cases, however, partial sequencing was done of the RNA found in clinical samples; for example, Archard et al.²⁰ identified the amplified sequence as CVB.

Not all the viral genomic studies have been positive. One investigation involving a nested PCR failed to find evidence of EV RNA in 287 heart biopsy specimens from 38 patients with dilated cardiomyopathy and 39 patients with heart failure of unknown cause.⁹² At least two other studies have also resulted in negative findings.^{251,369} The lack of consistent reproducible results regarding the presence of enteroviral genome in tissue from patients with cardiomyopathy indicates that further studies are needed under careful, blinded conditions.

Muscle Disease Including Pleurodynia

The relationship of EV to inflammatory muscle diseases was initially recognized because of the myotropism of coxsackieviruses in suckling mice. This observation was fueled by the association of these viruses with epidemic pleurodynia on the Danish island of Bornholm. The latter disease, called *Bornholm disease*, is an acute febrile illness with myalgia, especially involving the chest and abdomen, but without muscle weakness.

It has occurred as an epidemic and also sporadically in various locales. Relapses can occur. CVB3 and B5 are the most frequently recognized causative agents, although other EVs have also been isolated.⁴⁴⁶ The limited information from muscle biopsy findings suggests that the inflammation in this disease may be confined to the endomysial part of the muscle and, therefore, is not a true myositis.⁸⁷

Enteroviruses have been implicated in acute and chronic inflammatory muscle disease. The acute diseases, which are usually called *acute polymyositis* or *myositis*, are characterized by fever with myalgia, elevated muscle enzymes, and, at times, myoglobinuria. Chronic inflammatory muscle diseases, which are generally classified as polymyositis, dermatomyositis, or inclusion body myositis, have a subacute to chronic progressive weakness with a distinctive pathology on muscle biopsy. Dermatomyositis is distinguished from the other two inflammatory myopathies because it is associated with a characteristic rash.

The causes of chronic inflammatory myopathy are generally unknown. Hypotheses concerning the etiology of polymyositis and dermatomyositis include a direct virus infection, especially an EV infection, or an autoimmune process in which the virus infection triggers a reaction against muscle (see Pathogenesis earlier). That coxsackieviruses cause acute and chronic inflammatory myopathy in experimental animals provides additional support for their involvement in human inflammatory muscle diseases. Investigations of these model systems may help clarify the pathogenesis of these diseases in humans.

Enteroviruses have been isolated from cases of inflammatory myopathies, but these isolations have generally been rare and from single cases with acute³³ or atypical clinical pictures.³⁸⁹ The inability to isolate virus from cases of chronic inflammatory myopathy has raised the possibility of a restricted expression of the virus with little infectious virus present. For this reason, investigators have probed muscle tissue from patients with inflammatory myopathy for picornaviral genome. Some reports involving slot blot or *in situ* hybridization studies of muscle tissues from patients with inflammatory myopathies have shown positive results using EV-specific probes.⁴⁴⁴ In some cases, the product amplified in an RT-PCR has been identified as CVB sequence.²¹ In contrast, other studies using RT-PCR and nucleic acid hybridization have found negative results.^{245,247,328} It remains a possibility that an EV could trigger an autoimmune inflammatory muscle disease and then disappear. Studies regarding the possible role of EV in chronic fatigue syndrome have similarly failed to find reproducible evidence of EV involvement.⁸⁷

Of special interest with respect to the issue of EV involvement in inflammatory muscle disease is the observation that patients with immunodeficient states can manifest a disease similar to dermatomyositis with an accompanying persistent echovirus infection.^{412,419} It should be noted, however, that questions have been raised whether these patients had a true myositis (i.e., inflammation of the muscle) or a fasciitis with interstitial inflammation in the endomysium.⁸⁷ The inflammatory muscle disease is associated with a chronic encephalomyelitis as well as a more disseminated disease in which EV, especially echoviruses, can be cultured from the spinal fluid (see Clinical Features: Meningitis and Encephalitis earlier).⁴⁵¹ Although virus has occasionally been isolated from affected muscle, it remains unclear whether the dermatomyositis syndrome in patients who are immunodeficient is a result of

direct virus invasion of the muscle or an immune-mediated disease associated with virus persistence. The existence of this syndrome similar to dermatomyositis demonstrates that echoviruses, and perhaps other EVs, can produce a chronic myositis in humans that is associated with persistent infection and chronic inflammation.

Diabetes

Both genetic and environmental factors, including EV infection, have been implicated in the cause of insulin-dependent diabetes. A number of epidemiologic and serologic studies have demonstrated a relationship between EV infection and the development of diabetes. D'Alessio⁸⁴ found that 15 of 84 cases (17.8%) of newly diagnosed insulin-dependent diabetes had evidence of IgM antibody against CVB, compared with 5 of 71 controls (7.0%). The individuals with IgM antibody were especially common in association with human leukocyte antigen (HLA)-DR3 positivity. A prospective study in Finland found a greater incidence of serologic conversion of EV antibodies among children who developed insulin-dependent diabetes than among those who did not.¹⁸⁷ The antibody present in the prediabetic period was directed against a number of different EV serotypes, including CVA9, B1, B2, B3, and B5.³⁵¹ At times, the EV antibodies are associated with autoantibodies to GAD₆₅ and other important targets.

Rare, but well-documented, isolations of CVB4 have come from the pancreases of patients with acute-onset as well as fatal cases of insulin-dependent diabetes.^{341,345} Some of the isolates have been demonstrated to be diabetogenic when inoculated into certain mouse strains⁴⁴¹ and nonhuman primates.⁴⁴² Patients dying from coxsackieviral myocarditis can have an associated pancreatitis, including isletitis. More recent investigations have involved probing tissues from patients for evidence of EV genome. An *in situ* hybridization study showed evidence of EV genome in the islets of autopsy pancreases from 7 of 12 newborn infants who died of fulminant CV infection (and 6 of the 7 had isletitis), in the islets of autopsy pancreases of 4 of 65 adults with type 1 diabetes, and in one of the pancreatic control tissues from 40 nondiabetic patients.⁴⁴⁰

Although it is likely that EVs are capable of causing diabetes mellitus in animals and humans, it remains unclear how often this occurs in humans and what if any immune mechanisms are involved.

Eye Infections

Acute hemorrhagic conjunctivitis is characterized by a short incubation period of 24 to 48 hours preceding a rapid onset of unilateral or binocular symptoms and signs. Patients manifest excessive lacrimation, pain, periorbital swelling, and redness of the conjunctiva (from subconjunctival petechiae to frank hemorrhages).⁴³⁸ Keratitis with accompanying pain and possible visual impairment as well as anterior uveitis may be seen. The epidemic disease can also be associated with nonophthalmic symptoms and signs, such as neurologic dysfunction (see Clinical Features earlier) and respiratory and gastrointestinal disturbances. The disease usually resolves without sequelae in 1 to 2 weeks.

The first pandemic of acute hemorrhagic conjunctivitis was recognized in 1969 in Africa. Within 2 years, two EVs, a new antigenic variant of CVA24 and a previously unknown EV serotype designated EV70, were implicated as causative

agents responsible for the epidemics of this disease.²⁵² During the first pandemic from 1969 to 1971, hundreds of millions of people were likely to have been infected. Subsequent epidemics of acute hemorrhagic conjunctivitis have continued in various locations throughout the world. Other EVs have also been recognized as causes of acute hemorrhagic conjunctivitis (e.g., echovirus type 7)³⁶³ and as causes of sporadic conjunctivitis and keratoconjunctivitis.²¹³ The ocular disease caused by EV is often indistinguishable from acute hemorrhagic conjunctivitis caused by various adenovirus serotypes.

Respiratory Infections, Herpangina, and Hand-Foot-and-Mouth Disease

Enteroviruses are a common cause of respiratory illnesses. Enteroviruses were isolated in 1.7% of 3,119 respiratory specimens submitted for viral culture from 1983 to 1994⁷⁰ and in 6.4% of all the viruses that were isolated from these specimens (54 of 838). Respiratory illness occurred in 15% of EV infections collected by the WHO from 1967 to 1974¹³⁷ and 21% of cases from the CDC obtained from 1970 to 1979.¹⁸ The EVs implicated in these respiratory infections included CVA (12.4%), CVB (20.3%), and echoviruses (12.6%).¹³⁷

Enteroviral respiratory infections are more frequently associated with upper respiratory infections (e.g., the common cold, croup, and epiglottitis) than with lower respiratory infections (e.g., pneumonia). The infections are frequently subclinical, but if they cause clinical disease it tends to be self-limited and mild, with a short incubation period of 1 to 3 days. More severe lower respiratory infections may be related to a higher dose of virus in the inoculum. In a series of infants with CVB infections, 30 of 77 patients had marked abnormalities (e.g., interstitial inflammation and hemorrhage), and 12 had virus isolated from the lung.²⁰⁹

Herpangina is a febrile illness of relatively sudden onset with complaints of fever and sore throat. Characteristic lesions are found on the anterior tonsillar pillars, soft palate, uvula, and tonsils, and on the posterior pharynx. The illness, which has a predilection for the young, is usually self-limited and disappears within a few days. At times, the disease is associated with more significant clinical abnormalities (e.g., meningitis). Hand-foot-and-mouth disease is an illness associated with vesicular lesions of the hands, feet, mouth, and, at times, buttocks.

A number of EVs have been identified as causes for herpangina, including CVA and B serotypes; echovirus types 6, 9, 11, 16, 17, 22, and 25;⁷⁰ and EV71. The main causes of hand-foot-and-mouth disease are CVA10 and A16 and EV71.¹³⁷ The pathogenesis of the lesions seen in herpangina is not clear; however, experimental infection of rhesus monkeys with CVA4 may provide a model system for the study of the pathogenesis of herpangina. In this system, ingestion of the virus by the oral route leads to multiplication in the lower gastrointestinal tract, followed by viremia, and then multiplication in the oropharynx.³⁷⁶

Neonate and Infant Disease

Neonates are at increased risk from enteroviral infections. This increased susceptibility is present in humans as well as experimental animals infected with varied EVs.⁷¹

The increased risk of neonates to EV infection was apparent in the prevaccine era with respect to PV. Although the incidence of paralytic disease among neonates approached 40%

born to mothers with poliomyelitis at the time of delivery, the overall incidence of neonatal poliomyelitis was an infrequent occurrence, perhaps related to the protective effect of maternal antibody.⁴³¹ Neonatal poliomyelitis generally had a shorter incubation period and a higher case fatality rate than found with disease later in life, demonstrating the increased susceptibility of immature hosts to EV infection. Infection of the mother early in gestation was associated with an increased risk of abortion, stillbirth, and prematurity.⁷¹

Nonpolio EVs are a not infrequent cause of infection in neonates and infants. In a series from the CDC, EV isolates from patients younger than 2 months of age included echoviruses (51%), CVB (45%), and CVA (4%).²⁸⁸ Echovirus serotypes included 4, 9, 11, 17 to 20, 22 (now classified as human parechovirus 1), and 31.

The most frequent presentation in the neonate with nonpolio EV is asymptomatic infection.¹⁹⁶ Symptomatic cases most commonly manifest a self-contained febrile illness, at times associated with irritability and nonspecific signs of infection, making EV infection a leading cause of fever in the infant. A rash of variable character is seen in more than 30% of cases.⁴ More serious infections can be seen, with the peak of symptoms correlating with viremia.⁸⁶ Nonpolio EVs are the most frequently identified cause of aseptic meningitis in infants younger than 1 month of age and are believed responsible for more than one-third of these cases.³⁰¹ An increased susceptibility of the neonatal CNS to CV infection may be related to the virus's predilection for neonatal stem cells.¹¹¹ In a small series of patients with pneumonia in the first month of life, EVs were implicated in 15% of cases (6 of 40).⁵ Usually, the mother has a history of fever or respiratory symptoms a week before the delivery, although mothers can be asymptomatic or have a more severe disease.

One of the serious infections caused by EVs is a sepsis-like disease. In one series, EVs were implicated in 65% of infants younger than 3 months of age admitted to the hospital for suspected sepsis.⁸⁵ In another series, evidence was seen of enteroviral genome in 80 of 345 infants younger than 90 days of age admitted to a medical center with suspected sepsis.⁵⁰ A number of other studies have yielded similar results, emphasizing the importance of EV as a cause for a sepsis-like syndrome among neonates and infants.⁸⁶ In fact, EVs tend to be a more common cause of this syndrome than bacteria in the summer and fall.⁵⁰ There may be extensive multiorgan involvement in severely affected cases, especially ones that go on to a fatal outcome; the organs affected include liver, lung, heart, pancreas, and brain.

The incidence and severity of EV infections among infants can be better appreciated by reviewing a study conducted in Nassau County, New York, from 1970 to 1979.²⁰⁹ Of 153,250 live births, 77 infants younger than 3 months required hospitalization for CVB infection. These 77 cases were from a pool of 602 infants who tested positive for CVB, demonstrating the high frequency of CVB infection in infants. The attack rate might have been even higher than was found, because the positive samples from this study were from only a limited number of infants hospitalized in the community. A total of 24 mothers had evidence of a viral-like infection occurring within a period from 10 days before delivery to 5 days after delivery. The most common syndrome that was seen was aseptic meningitis. Some of the infections in the infants were very serious, as evidenced by the finding that eight children died from

overwhelming CVB infection. All but one of these eight had evidence of myocarditis.

Severe EV disease in the young is associated with an early age of illness, prematurity, a more severe illness in the mother, multiorgan disease, low socioeconomic status, bottle-feeding, specific EV types, and an absence of neutralizing antibody to the pathogen.⁴ The level of maternal neutralizing antibody appears to be important both for determining the risk of developing infection and for modulating disease severity.⁷ Long-term sequelae following neonatal myocarditis or CNS infection appear infrequent.^{4,357}

Nonpolio enteroviral infection can affect the fetus, inducing clinical abnormalities and causing overt disease in the neonate. Reports exist of abortion and stillbirth associated with maternal enteroviral infections, although these are infrequent.⁴ The relationship between maternal EV infection and congenital anomalies in the newborn remains unclear.

A number of routes exist by which EV can cause neonatal disease. Studies have found evidence of placentitis and viral infection in fetal tissues.⁴ Virus can enter the placenta or fetus from contaminated maternal blood, feces, or vaginal secretions, which can occur during pregnancy, with virus penetrating the fetal membranes, or at the time of the delivery. In addition, infection of the neonate can result from a viremia, because EVs have been cultured from cord blood,¹⁹⁹ but it is unclear how often this route of transmission occurs. Infection can also occur from virus shed by other neonates or hospital staff in the nursery. In cases involving nursery outbreaks, implementation of infection controls (e.g., strict hand washing and the isolation of affected patients) has a role in prevention of new cases.

DIAGNOSIS

Differential and Presumptive Diagnosis

The process of diagnosing an EV infection or establishing that an EV infection produced a particular clinical syndrome can be complicated and challenging. This problem results from the biology and epidemiology of EV infections, as well as from limitations in current diagnostic methodologies. Although it is possible to demonstrate that a person is infected with an enterovirus, this association does not necessarily prove likely disease causation. On the other hand, a presumptive diagnosis in certain epidemiologic and clinical situations can be possible with a high degree of certainty on clinical grounds alone.

Several related biological properties complicate the diagnosis of EV-induced disease. The first is that most virus replication and infection typically occur in the respiratory and gastrointestinal tract. These infections are often asymptomatic, with few if any systemic clinical signs. Because these infections are extremely common, even random sampling of healthy individuals can demonstrate EV infections at substantial rates. For this reason, the simple recovery or detection of virus from certain nonsterile sites does not establish a firm linkage to disease, and it may be merely coincidental.

A second difficulty is that even when illness results from the EV infection, most of the signs and symptoms are relatively generic and usually lack specificity. The collection of appropriate clinical specimens for virus isolation or detection is critical to laboratory confirmation of EV infection. For example, the exclusive use of CNS or cardiac specimens to diagnose

meningitis and encephalitis limits the sensitivity for detection of infection. For example, although it is possible to detect EV in the CSF from meningitis cases, it is uncommon to find virus in the CSF from cases of encephalitis wherein is seen a reasonable suspicion of EV as the cause; in other cases, the virus can be readily recovered from CSF, such as during the recent outbreaks of fatal EV71 encephalitis.¹⁷ In general, however, the specimen with the highest sensitivity for establishing an acute infection is a stool specimen, regardless of clinical presentation.²⁸¹ The difficulty with virus detection in some clinical conditions may be further compounded because virus shedding from the gastrointestinal tract may stop before the onset of symptoms and, therefore, sensitivity for virus detection may be lower.

Sometimes a presumptive diagnosis can be made on the basis of limited information because of the pronounced seasonality of EV infection in temperate latitudes and the tendency for EV to cause community outbreaks. For example, cases of aseptic meningitis occurring during the late summer and early autumn have a high probability of EV etiology. In this situation, a presumptive diagnosis of an EV infection could be made on the basis of signs and symptoms, exclusion of other nonviral pathogens, and evidence of characteristic cytopathology of inoculated cell cultures or detection from some nonsterile site. Another example pertains to epidemic acute hemorrhagic conjunctivitis; in this case, the identification of an EV (either CVA24 variant or EV70) precludes the need for further testing of specimens from other patients in that community with similar symptoms.

Laboratory Diagnosis

Molecular Detection

The application of molecular biology techniques to clinical virology has significantly changed approaches to EV diagnostics (see Epidemiology earlier). Because of distinct advantages in speed, many of these procedures have already supplanted traditional methods of detection and characterization. Continued development and refinement of these procedures will undoubtedly lead to even further application of the methodologies to a broader spectrum of EV diagnostic problems and, ultimately, into routine primary usage.

As with virus isolation and serotyping, the molecular methods attempt to detect the presence of EVs in a specimen and, in some procedures, to further characterize the detected virus. The techniques can be grouped on the basis of their infrastructure and technical requirements and the types of specimens to which they are applicable. The most commonly used tests are based on the PCR, which is used primarily to detect EV genome in cell cultures, clinical specimens, and biopsy or autopsy tissues.³¹⁷ The newest procedures utilize genomic sequencing for the characterization of EV at the highest levels of specificity.

By far the most common use of PCR for EV diagnosis is the direct detection of virus in clinical specimens.^{214,317,323,360} Numerous variations on the details of the procedures are found, but all methods that can generically detect EV have several common features. The most important property of these tests is that the primers are targeted to amplify the 5' UTR of the virus genome (Fig. 17.10). Many different primers targeted to this region have been published, targeting different sequences and providing different product sizes. Many of these primers, however, have not been completely evaluated on a

large number of clinical samples to confirm reactivity with all EV serotypes and strains within serotypes, and therefore, they have not been validated sufficiently for diagnostic use.²⁹¹ The major advantage of the pan-EV PCR is that rapid detection of an EV is possible, even with very small amounts of clinical specimens such as spinal fluid. It is also possible to detect EVs that do not readily grow in cell culture. As with all PCRs, the sensitivity of amplification of RNA from biological specimens is extremely variable, depending on the nature of the specimen. Although the PCR procedure can be shown to give a positive result even from only one or a few copies of viral RNA, it is not unusual for the sensitivity to be many orders of magnitude lower in certain specimens (e.g., stool). For this reason, despite the theoretic advantage of the PCR to greatly improve EV detection from clinical specimens, the gains in practice are much more modest (e.g., with spinal fluid) or nonexistent (e.g., with stool).³⁸⁸

By changing the target for amplification, it is possible to characterize a particular EV using the PCR. Because the antigenic property of viruses that defines serotype is a property of the viral capsid proteins, certain sequences correspond to this conserved antigenic property within the capsid-coding region of the virus. Extensive studies of the capsid region of PV isolates have led to the design of primers that can selectively amplify isolates from a single serotype but not from other isolates of heterologous serotypes.²²³ This is accomplished, despite the high rate of synonymous nucleotide substitutions, through the use of inosine in the primer synthesis. In an analogous manner, the ability of PV to uniquely bind to the CD155 is also an intrinsic property of the capsid proteins. The amino acids that are involved in receptor binding have been well characterized from studies of the three-dimensional structure of the virion. When primers are designed that correspond to these presumably PV-specific sequences, amplification is observed with all PV isolates but not with other EVs.²²⁴ It should be possible to extend these principles to other EV receptor groups and serotypes and to provide tools for rapid serotype characterization of EVs without the requirement for cell culture procedures. Nucleic acid probes, including the use of RNA probes to improve sensitivity, the introduction of nonradiochemical labeling of probes, and the application of these techniques to *in situ* hybridization in myocardial tissue,¹⁶⁶ have been particularly useful for understanding the cytopathology of EV infection, especially in studies of myocarditis. The technique, however, is relatively insensitive and cannot be used to identify the EV serotype in a specimen because of probe binding to related serotypes.

A goal in virus identification is knowledge of the sequence of the viral genome. Encoded within this sequence are determinants for all the biological properties that are attributable to a given virus. Therefore, the nucleic acid sequence information of a virus represents its ultimate characterization. All important information about a virus could potentially be obtained directly by PCR in conjunction with nucleic acid sequencing if all the molecular correlates of viral phenotypic determinants were understood. At present, however, the genetic location for many properties of the virus remains uncertain. Nevertheless, it is possible at present to use sequence information to assign an EV isolate to a particular serotype.³¹¹ The molecular typing system is based on RT-PCR and nucleotide sequencing of all or a portion of the genomic region encoding VP1. The serotype of an unknown isolate is inferred by comparison of the

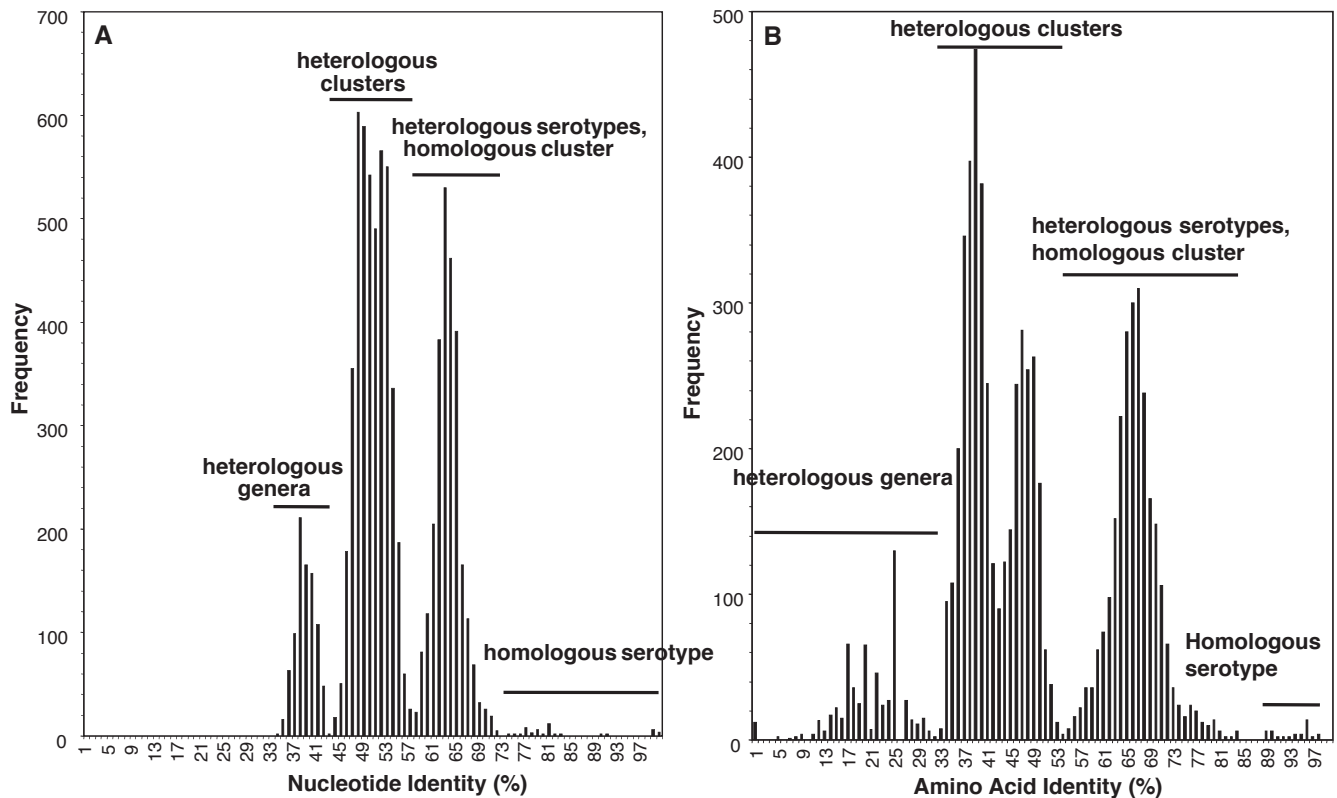

FIGURE 17.11. Serotype identification using sequence data. Frequency distribution of pairwise identity scores for comparison of VP1 nucleotide and deduced amino acid sequences. Serotype identification of an isolate can be achieved by comparing the sequence of the isolate with known sequences in VP1 for all serotypes and looking for identities of greater than 75% in nucleotide sequence or greater than 88% in amino acid. **A:** Nucleotide sequence distribution. **B:** Amino acid sequence distribution. (From: Oberste MS, Maher K, Kilpatrick DR, Flemister MR, Brown BA, Pallansch MA. Typing of human enteroviruses by partial sequencing of VP1. *J Clin Microbiol.* 1999;37:1288–1293.)

VP1 sequence with a database containing VP1 sequences for the prototype and variant strains of all human EV serotypes. The following guidelines have been suggested:

- (i) a partial or complete VP1 nucleotide sequence identity of $\geq 75\%$ ($>85\%$ amino acid identity) between a clinical EV isolate and serotype prototype strain may be used to establish the serotype of the isolate, on the provision that the second highest score is $<70\%$; (ii) a best-match nucleotide sequence identity of $<70\%$ may indicate that the isolate represents an unknown (that is, new) serotype; and (iii) a sequence identity between 70% and

75% indicates that further characterization is required before the isolate can be identified firmly.³¹⁶

Using these guidelines, strains of homologous serotypes can be easily discriminated from heterologous serotypes and new serotypes can be identified (Fig. 17.11). This method can greatly reduce the time required to type an EV isolate and can be used to type isolates that are difficult or impossible to type using standard immunologic reagents. The technique is also useful to rapidly determine whether viruses isolated during an outbreak are epidemiologically related.

FIGURE 17.10. Enterovirus nucleotide and amino acid sequence variation, and location of primers used for virus detection and identification.

A: Sequence conservation at sites in the enterovirus (EV) 5' nontranslated region (NTR) that are targeted by published real-time reverse transcriptase-polymerase chain reaction (RT-PCR) primers. The consensus sequence at each site and the sequences of the widely used Rotbart primers and probe are indicated for comparison. Mismatches between a primer and the human enterovirus consensus are underlined. Numbers indicate nucleotide positions relative to the genome of poliovirus 1, Mahoney strain (GenBank J02281). **B:** Sequence conservation at sites in the EV 5' NTR that are targeted by the published nucleic acid sequence-based amplification (NASBA) methods, as in panel **A**. **C:** Nucleotide sequence variation across the enterovirus genome. Complete genome sequences for reference strains of all human enterovirus serotypes were aligned, the sequence identity within each window of 18 residues was plotted versus the nucleotide position, and the window was advanced in one-residue increments across the genome. An expanded view of the 5' NTR analysis is shown in the upper plot. Peaks labeled 1–5 are sites commonly targeted by enterovirus molecular detection assays. **D:** Enterovirus genome map. Boundaries of mature protein products are approximate. **E:** Amino acid sequence variation across the enterovirus genome. Deduced polypeptide amino acid sequences for reference strains of all human enterovirus serotypes were aligned; the sequence identity within each window of six residues was plotted versus the amino acid position and the window was advanced in one-residue increments across the genome. **F:** Locations of RT-PCR products used for molecular serotyping.

Virus Isolation

Many of the detailed procedures for the established laboratory diagnosis of EV infections using virus isolation have been described.¹³⁵ The traditional techniques for detecting and characterizing EV rely on the time-consuming and labor-intensive procedures of viral isolation in cell culture and neutralization by reference antisera. Isolation of EV from specimens using appropriate cultured cell lines is often possible within 2 or 3 days and remains a very sensitive method for detecting these viruses. The best specimens for isolation of virus are, in order of preference, stool specimens or rectal swabs, throat swabs or washings, and CSF. Throat swabs or washings and CSF are most likely to yield virus isolates if they are obtained early in the acute phase of the illness. For cases of acute hemorrhagic conjunctivitis, the best specimens are conjunctival swabs,⁴³⁸ although occasionally virus can be isolated from tears.⁴³⁹ Since the major pandemic in 1981, however, isolation of EV70 from patients with acute hemorrhagic conjunctivitis has been very difficult, and molecular methods provide the only sensitive method to detect this agent.³⁷⁴

The procedure for virus isolation involves inoculation of appropriate specimens onto susceptible cultured cells. No single cell line exists that is capable of growing all human enteroviruses. It is common practice to use several types of human and primate cells to increase the spectrum of viruses that can be detected.⁶⁹ Even with a variety of cells, however, several CVA serotypes fail to propagate in culture. The coxsackieviruses, including those that do not grow in cell culture, can be isolated and propagated in suckling mice.

As a consequence of current PV eradication activities and the importance of PV as a public health problem, specific diagnostic procedures have been developed to detect this virus. In general, PV grows well on a variety of primate and human cell culture lines, but it cannot be distinguished from other EVs solely on the basis of cytopathic effect. Polioviruses are unique in the use of CD155, which is distinct from receptors used by all other EVs to infect cells. This receptor has been transfected and expressed in a murine cell line that normally cannot be infected by most EVs but is permissive to viral replication when the viral genome is present within the cell. One of these transfected murine cells, L20B, can grow PV and has been exploited selectively to isolate PV, even in the presence of other EVs.¹⁷¹ When a specimen is inoculated onto these cells and a characteristic EV cytopathic effect is seen, the virus can be presumptively identified as a PV. A few strains of certain nonpolio EV serotypes are able to grow on the parent murine cells, however, and therefore growth on L20B cells is not a definitive identification of PV, and confirmatory testing is required.

In routine diagnostic testing, all EV growth in cell culture is detected by its cytopathic effect, and the isolate is typically confirmed as a specific EV by neutralization with type-specific antisera, by immunofluorescence with type-specific monoclonal antibodies, or by PCR coupled with sequencing. For clinical management of routine cases, it is seldom critical to identify the specific nonpolio EV type. A high index of suspicion for an EV infection can be developed by reflecting on the clinical picture, the virus isolate's cytopathic effect and cell culture systems utilized, and knowledge of basic EV epidemiology.

Antibody Tests

Serologic diagnosis of EV infection can be made by comparing titers in acute and convalescent phase (*paired*) serum specimens. In general, however, EV serodiagnosis is more relevant to epidemiologic studies than to clinical diagnosis (see Epidemiology earlier). The most basic serologic test is that of neutralization in cell culture. Many serologic studies rely on the detection of IgM antibody as evidence for recent EV infection, and this is now widely used as an alternative to the neutralization and complement fixation test. Several groups have developed an enzyme-linked immunosorbent assay (ELISA) for EV-specific IgM.^{30,263} These tests have been found positive for nearly 90% of culture-confirmed CVB infections and can be performed rapidly. The ELISA has been successfully applied for epidemiologic investigations of outbreaks,¹³⁰ as well as for specific diagnostic use.⁹⁰

In most cases, the IgM ELISA test is not serotype specific. Depending on the configuration and sensitivity of the test, from 10% to nearly 70% of serum samples show a heterotypic response caused by other EV infections. This heterotypic response has been exploited to measure broadly reactive antibody, and the assay used to detect EV infection generically.^{42,384} In attempting to characterize the exact nature of the response using different antigens, it is clear that the human immune response to EV infection includes antibodies that react with both serotype-specific epitopes and shared epitopes.¹²⁰ Despite this problem, which is inherently biological, a fairly high concordance of results remains between assays of different configurations.¹⁶² In summary, the IgM assays that are generally used in epidemiologic studies have very good sensitivity and appear to be very specific for EV infection; however, these assays detect heterotypic antibodies resulting from other EV infections and, therefore, cannot be considered strictly serotype specific.

PREVENTION AND CONTROL

Treatment

Although no currently available drug treatment for enteroviral infections is in clinical use, the effectiveness of a variety of drugs *in vitro*, as well as in animal models, has been documented. In addition, varied new directions for future therapeutic intervention are being pursued.

Several potential therapies (e.g., IFN and antiviral antibody) target early stages in the virus life cycle, such as spread. IFN- α and IFN- β have been found to be effective in CVA24 *in vitro* infections.²⁴³ Pilot studies have been conducted administering intravenous immunoglobulin in neonates suspected of having enteroviral infection.⁷ Pooled immunoglobulin delivered intravenously or via a shunt into the spinal fluid has also been used in patients who are agammaglobulinemic with chronic encephalitis and meningitis associated with nonpolio enteroviruses. Patients who are immunodeficient with persistent EV infections, including PV infections, represent a particular challenge to effective treatment. Although intravenous immunoglobulin may protect these patients from poliomyelitis and may appear to stabilize and improve some of the infections, the disease may progress; most of these infections, however, spontaneously cease. In some cases, efficacy may be limited by inadequate amounts of the relevant antibody in the immunoglobulin pool (e.g., if the infection involves an

unusual and rare EV serotype), as well as problems in the delivery of adequate levels of antibody to the infected cells. One report documented the failure to clear persistent PV excretion despite treatment with intravenous immunoglobulin, breast milk, and ribavirin.^{261a} Interestingly, a successful clearance of PV may apparently follow intercurrent diarrheal infections caused by other pathogens, perhaps because of damage to gut lymphoid tissue, which acts as a main site of PV replication.²²²

A number of specific antiviral compounds have been developed to target enteroviral proteins and steps in the virus's life cycle. The *WIN compounds* and related derivatives, which were originally shown to be effective against rhinovirus, have shown the most consistent results and have been those most studied mechanistically. These drugs bind a hydrophobic site near the surface of the virion called the *pocket*,⁴⁴⁷ which lies in the floor of the *canyon* where the virion binds to the cellular receptor. By binding to the pocket, these compounds are believed to interfere with viral attachment and uncoating. Variations in activity of WIN compounds against different picornaviruses are presumably related to the particular fit of the drug into the pocket of a specific EV strain. Oral administration of WIN 54954 significantly decreased the number of upper respiratory infections following challenge with CVA21 (i.e., 3 of 27 patients in the treated group had an upper respiratory infection versus 15 of 23 in the placebo group) with decreased associated symptoms and viral titers.³⁶⁷ Adverse reactions, however, curtailed further investigations with this drug. Pleconaril or VP 63843 is a more recently developed pocket-binding compound with a broad *in vitro* inhibitory activity against 95% of the 215 nonpolio EVs that were tested.³³² Significant activity was noted against some serotypes, such as echovirus 11. A randomized, double-blind study involving the administration of pleconaril following a challenge with CVA21 showed statistically significant decreases in viral shedding in nasal secretions, nasal mucous production, and total respiratory illness symptom scores in patients treated with pleconaril compared with subjects treated with placebo.³⁶⁷ Another phase II trial of the same drug against enteroviral meningitis showed a statistically significant decrease in disease duration (9.5 days in the placebo group versus 4.0 days in the controls).³⁵⁹ A subsequent study, however, failed to have the statistical power to show efficacy in infants with enteroviral meningitis.⁶ A problem with all of these antiviral compounds is that mutant viruses resistant to the drug can arise. In the case of resistance to rhinovirus, the mutant viruses tend to have bulky amino acid substitutions that sterically block entry of the drug into the pocket.¹⁵⁴ These mutant viruses may not be as significant a problem as expected, because drug-resistant CVB3 mutants that appeared in tissue culture following exposure to the WIN compounds tended to be attenuated when inoculated into mice.¹³⁸

Enviroxime is an antiviral drug that targets nonstructural protein 3A, leading to a block in the synthesis of plus-strand viral RNA. Although this compound inhibits EV and rhinovirus *in vitro* infections, it is toxic and not effective in humans.⁹⁸ Resistance to enviroxime is determined by changes in the amino acid at position 30 in protein 3A.¹⁵⁵

An antiviral strategy promoted recently involves the use of drug-sensitive dominantly inhibitory viruses, generated as a result of a targeted drug treatment, which interfere with growth of drug-resistant viruses.⁸³ Regions of the virus that can serve as targets for drugs that lead to the generation of these dominant

defective viruses include (a) the capsid and polymerase coding region, because of the proteins' oligomeric properties (i.e., there is interference during interactions with the respective wild-type protein); (b) cre and VPg (genome-linked virus protein), perhaps because their malfunction leads to inhibitory intermediates; and (c) 2A, perhaps because the uncleaved intramolecular cleavage of VP1–2A is inhibitory during assembly of the virus capsids. The 2A proteinase seemed to be an especially attractive target because of its inability to be rescued *in trans* and the dominant inhibition of the uncleaved product on virus growth.

The administration of small interfering RNA (siRNA) has also been examined as a possible strategy for control of EV infections. This approach has been used to inhibit *in vitro* infections of PV as well as CVB3.^{10,128} The use of a pool of siRNA to target multiple sites throughout the virus genome may be able to limit the emergence of resistant viruses arising from mutations. The possibility of designing an siRNA that is effective against many closely related EV makes this an especially attractive approach for human infections. As with all siRNA approaches, further testing in varied EV infections of animals and then humans is necessary, including the development of an efficient and appropriate delivery system.

Vaccines

Efforts have been initiated to develop a vaccine against EV71, and several approaches have been evaluated in animal models. Mice immunized with a DNA vaccine encoding VP1,^{402,430} or with synthetic peptides encoding B-cell epitopes from VP1,¹¹⁵ mount a neutralizing VP1-specific IgG response; passive transfer of vaccine-induced antibodies to neonatal mice conferred substantial protection against a normally lethal EV71 challenge.¹¹⁴ A virus-like particle (VLP) vaccine induced a strong and sustained neutralizing IgG response.⁷³ Finally, transgenic mice have been developed in which VP1 is expressed in the milk of nursing mothers; EV71-specific antibodies were induced in the suckling pups.⁷³ In both of the latter studies, the antibody responses protected neonatal mice against a normally lethal EV71 challenge.^{66,73}

Poliovirus Vaccine and Eradication

The PV field was fortunate to have more than one excellent vaccine, because both the killed intramuscular vaccine of Salk and the oral attenuated vaccine of Sabin were available. Both of these vaccines result in production of anti-PV antibody (Fig. 17.12) with subsequent protection from disease.³⁰⁰ Although there has been a continuing advocacy for one or the other vaccine over the years, it is clear that each has advantages and disadvantages (Tables 17.9 and 17.10) and that appropriate circumstances exist for the use of each. With the incidence of PV declining dramatically, the United States has switched from OPV to the exclusive use of IPV in 2000 (at 2 months, 4 months, 6 to 18 months, and 4 to 6 years of age). The main benefit for this change was the elimination of vaccine-associated paralytic poliomyelitis (VAPP), and subsequent studies have shown that this was accomplished.¹²

In 1988, in part based on the rapid progress of eradication activities in the Americas, the World Health Assembly unanimously adopted a resolution calling for the global eradication of PV before the end of the 20th century. This resolution was reaffirmed in May of 1999, 2004, and 2011, and an acceleration of activities was urged with particular focus on the

FIGURE 17.12. Serum and secretory antibody responses to oral administration of live attenuated polio vaccine and to intramuscular inoculation of killed poliovirus (PV) vaccine. (From: Ogra PL, Karzon DT. Formation and function of poliovirus antibody on different tissues. *Prog Med Virol.* 1971;13:156–193.)

remaining endemic areas. These accelerated activities include additional rounds of National Immunization Days, intensified surveillance in high-risk communities, and mopping up in focal reservoirs.

A progress report on the global efforts to eradicate PV is provided on a website of the WHO.⁴²⁷ Four fundamental components compose the strategy to eradicate PV.¹⁸⁵ First is the achievement and maintenance of high levels of routine immunization. With the accelerated activities resulting from the Expanded Program on Immunization of the WHO, routine coverage with three doses of OPV in children younger than 1 year of age reached nearly 90% of the world's children by 1990; however, maintenance of these levels has not been completely successful, and some erosion of routine immunization has occurred. Because of the inability of routine immunization to control PV circulation in many developing countries, the second element of the strategy is the use of National Immunization Days for the delivery of vaccine to all children younger than 5 years of age in a very short period of time, usually from 1 to a few days.³⁴ The mass immunization interferes with the spread of wild PV through a rapid increase in population

TABLE 17.9 Killed Poliovirus Vaccine: Advantages and Disadvantages

Advantages

- Safe because inactivation ensures no infectious virus exists
- Can be used in immunodeficient and immunosuppressed individuals
- Provides excellent systemic immunity

Disadvantages

- Requires intramuscular injection with repeated doses
- More expensive than live vaccine
- Potential hazards because of the use of wild seed virus in production
- Reduced intestinal immunity compared with natural infection

TABLE 17.10 Live Poliovirus Vaccine: Advantages and Disadvantages

Advantages

- Confers strong systemic and intestinal immunity
- Relatively inexpensive
- Provides herd immunity because the virus is excreted into the environment, expanding immunity
- Oral delivery
- Relatively safe

Disadvantages

- Can mutate to neurovirulent form, causing vaccine-associated paralytic poliomyelitis
- Contraindicated in immunodeficient and immunosuppressed individuals
- Requires monkeys for safety testing
- Can lead to circulating vaccine-derived polioviruses causing outbreaks of poliomyelitis

immunity and abruptly decreases the *chains of transmission* in a country. This strategy was used in many early immunization efforts in the 1960s and was applied successfully in Cuba to achieve and maintain the elimination of PV from that country following 3 successive years of annual campaigns.³⁵⁰ Multiple rounds in a given year are now routinely carried out for all endemic countries, and the National Immunization Days have grown in an extraordinary way as more countries have adopted this strategy. Some campaigns now represent the largest public health activities on record and often represent the largest multinational health events as well.

The third basic element is the use of surveillance based on cases of acute flaccid paralysis.³⁵ One of the major differences between the smallpox eradication program and the efforts to eradicate PV is the low rate of clinical disease following PV infection. Because less than 1% of infected susceptible individuals will develop paralytic illness, most infections are not clinically recognized. Therefore, unlike smallpox, where almost all infections were symptomatic, PV is difficult to detect; this is certainly a challenge to eradication efforts. To improve the sensitivity of detecting PV infection and yet achieve a practical system, surveillance was developed around the unique clinical presentation of paralytic poliomyelitis. To avoid the requirement for extensive neurologic examinations, which are not feasible in many developing countries, the surveillance was simplified to include any case of acute flaccid paralysis. This system reports many other diseases in addition to poliomyelitis, such as Guillain-Barré syndrome, transverse myelitis, and traumatic neuropathy. This loss of specificity, however, is compensated for by a gain in sensitivity, because most cases of true poliomyelitis are reported. The incidence of non-PV-induced flaccid paralysis is also used as an indicator of surveillance sensitivity (>2 cases per 100,000 population younger than 15 years of age is considered an operational indicator of adequate quality), although it is not clear if the expected rate is the same in different countries or would be expected to be constant over time. Regardless, acute flaccid paralysis surveillance has proved to be remarkably efficient for detection of wild PV circulation.

The remaining part of surveillance is focused on detection of the virus. Two stool specimens are collected from all cases of

acute flaccid paralysis and tested in a global network of laboratories to attempt isolation of PV.¹⁸⁴ The major advantages of this surveillance system are simplicity, practicality, and reasonable sensitivity for detection of PV. The major disadvantages are the requirements to (a) rapidly collect, transport, and test a large number of specimens from all areas of the world and (b) have high-quality laboratory testing. Despite these challenges, the global network of 146 laboratories was able to process more than 200,000 specimens in 2011 and provide this information in a timely manner to the Eradication Program.⁵⁹

The last element of the eradication strategy is the use of *mopping-up* activities.⁹³ This strategy focuses on an area or country where the previous three parts of the program have successfully reduced the number of PV cases to a small number, and where surveillance has localized the remaining reservoirs of transmission. It is then possible to intensify immunization activities in those targeted communities that contain the remaining circulating virus, or the last *chains of transmission*. These intensified activities usually involve active searches in communities for children, including house-to-house or boat-to-boat immunization.¹⁹ Teams visit all residences in the area and ensure that children are not missed. With further reduc-

tion of poliovirus circulation to only parts of a limited number of countries, a further increase in vaccine coverage was achieved by more focused Supplemental Immunization Activities. These immunization campaigns were focused on the remaining reservoirs of polio circulation within the endemic countries and conducted many times nearly year round. As a result of this intensified effort, by the end of 2011, only four countries continued to maintain polio circulation.

These elements of PV eradication strategy have proved successful in large parts of the world. Since the program began, almost all countries are now free of indigenous PV circulation. This can be seen in Figure 17.13, where in 1988 PV was found on all the continents (except Australia), with estimates of more than 350,000 cases of PV each year. In 2011, the number of countries with PV was only 16, and all of the Americas, Europe, and the Far East have been certified to be free of PV.⁵⁸ The only countries with endemic PV cases were in south Asia (Pakistan and Afghanistan) and Sub-Saharan Africa (Nigeria).

Numerous unknowns and potential obstacles remain to be faced in the eradication efforts. Because of the inherent insensitivity of detecting PV infection, it is important that surveillance quality be achieved and maintained for a period of time.

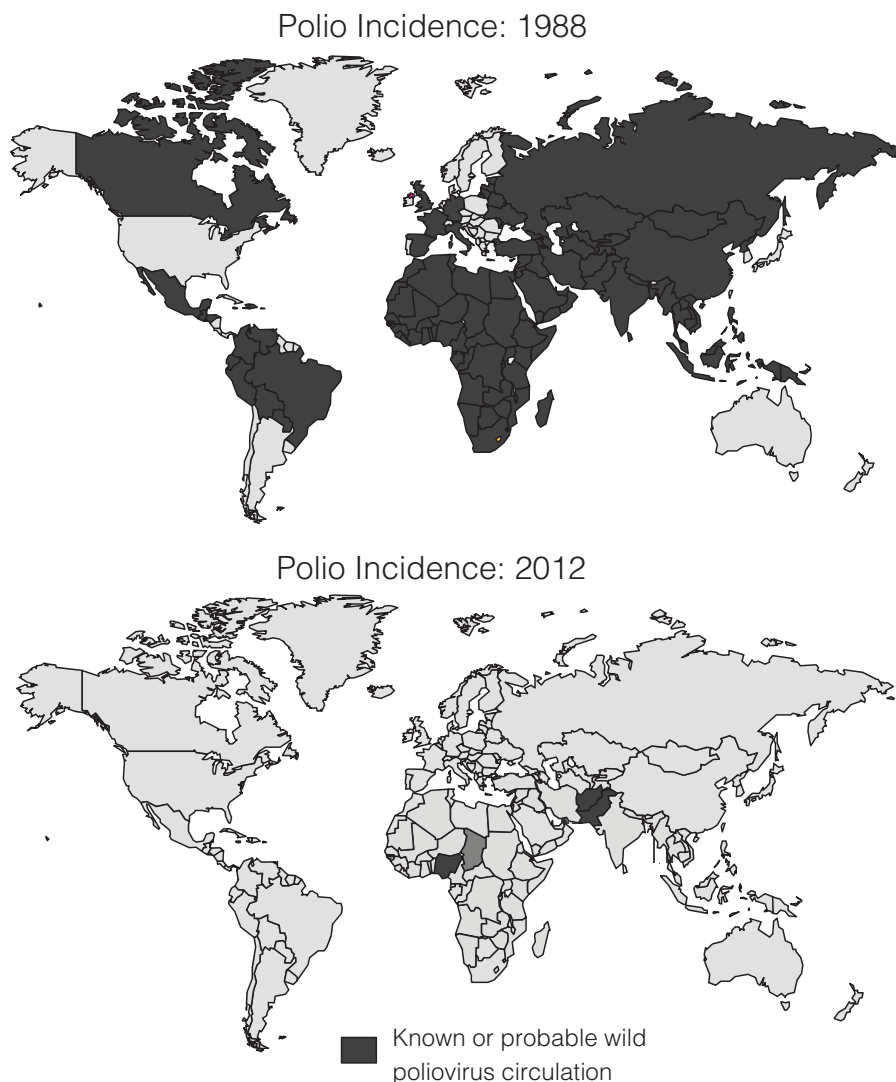

FIGURE 17.13. World map depicting the circulation of wild poliovirus (PV) for 1988 and 2012 as reported to the World Health Organization. In 2012, intermediate shaded country had eliminated indigenous transmission but following importation re-established transmission in the country for a period exceeding 12 months. (Adapted from Centers for Disease Control and Prevention, unpublished data.)

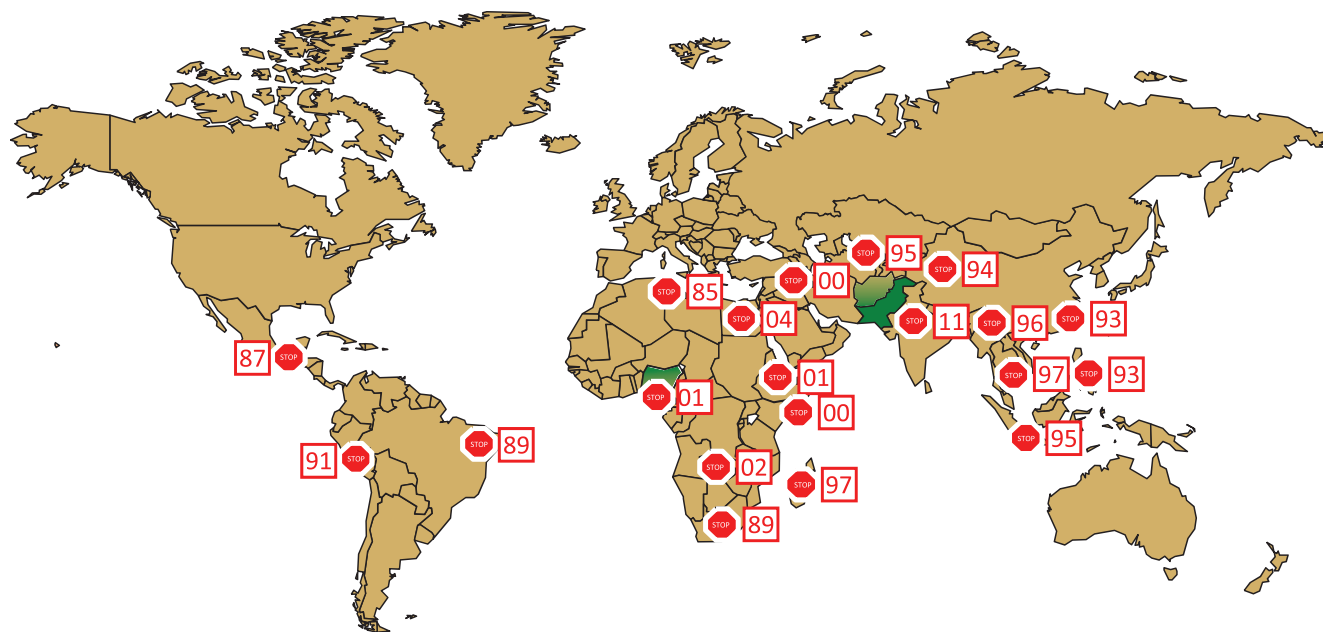

FIGURE 17.14. World map depicting type 1 poliovirus (PV) genotypes in different regions from 1985/2011 and the years in which the eradication occurred. Shaded countries represent remaining endemic circulation for the two remaining type 1 genotypes. Each symbol represents a distinct genotype that has been eradicated and the year when that occurred. (Adapted from Centers for Disease Control and Prevention, unpublished data.)

Although the exact length of time required to be assured of success is not known in all circumstances, the minimal requirement for certification is 3 years. Previous experience indicates that if excellent surveillance is achieved and maintained, PV genotypes that have not been detected for a period of 1 year will not be detected ever again. This has been true for more than three dozen genotypes that have been eliminated from circulation (Fig. 17.14).

After wild virus circulation is interrupted, the accidental release of viruses from laboratories or vaccine-manufacturing facilities will represent a significant risk to the PV-free world. Therefore, it will be necessary to institute proper containment of the virus. A plan for these steps of containment has been drafted and will be implemented in phases as eradication proceeds. In the first pre-eradication phase, preparation for later phases is to be undertaken by conducting an inventory of all institutions and laboratories that have wild PV or potentially infectious materials. This survey for wild PV and potentially infectious materials has been completed in the polio-free regions of the world and has been completed in more than 100 countries, including the United States.⁵⁵ Wherever possible, use of vaccine strains of PV in the laboratory should be substituted for wild strains. In the second phase, after the last wild PV has been isolated anywhere in the world, all work with wild PV will be done at a higher biosafety level of containment (BSL-3/polio). Once all countries and regions have been certified as being free of circulating PV, and once all laboratories have properly contained, referred, or destroyed their PV stocks and potentially infectious materials, the Global Certification Commission will declare wild PV eradicated. The last phase of containment will occur sometime in the future when the decision is made to stop vaccination with OPV. At that time, all infectious PV will need

to be in containment. The containment requirements for this last phase are being developed. In addition, the special containment needs associated with IPV production are being assessed. Of particular concern are the current use of wild strains and the associated risk of an accidental release of virus during vaccine production. One way to limit this danger that is under consideration and active development is to prepare the IPV from the live Sabin attenuated vaccine strains.⁷⁶

Once eradication of wild PV is achieved, the only disease caused by PV in the world will be as a result of the use of live OPV. In most parts of the world, the disease burden caused by VAPP already exceeds that of wild PV. In addition, the continued use of OPV poses a risk for outbreaks from vaccine-derived polioviruses (VDPVs). VDPVs are derived from OPV but differ from the OPV strains and from the frequent PV isolates seen soon after vaccination with OPV by having more than 1% nucleotide changes in the coding region for VP1. The demarcation of more than 1% is somewhat arbitrary but is consistent with the approximate 1 year of circulation of the virus. More recently, this definition has been modified for PV type 2 to be greater than 0.6% difference from the parent vaccine strain. Most OPV-like isolates and most PV excreted from patients with VAPP have less than 1% nucleotide change in the VP1 coding region and, therefore, are not classified as VDPVs because the duration of infection is short and because random mutations do not accumulate as observed with VDPVs. VDPVs fall into three groups: (a) circulating VDPVs (cVDPVs), (b) VDPVs isolated from individuals with immune deficiencies (iVDPVs), and (c) ambiguous VDPVs (aVDPVs) in which the source of infection is unknown.

Although recognized as a potential problem associated with OPV for more than 40 years, the occurrence of multiple

episodes involving cVDPVs within the last 12 years has explicitly demonstrated this risk. The first documented cVDPV outbreak of poliomyelitis occurred on the island of Hispaniola in 2000–2001, with 21 virologically confirmed cases in Haiti and the Dominican Republic, and with many more apparent cases from which no specimens were collected.^{218,220} Since this outbreak in Hispaniola, cVDPV outbreaks have occurred in numerous countries, including the large multiyear outbreak of type 2 cVDPV in Nigeria (<http://www.polioeradication.org/Dataandmonitoring/Poliothisweek/Circulatingvaccine-derivedpoliovirus.aspx>). In addition, cVDPVs have been recognized retrospectively in other countries, particularly Egypt, where the type 2 cVDPV was endemic for possibly 10 years.⁴³⁶ cVDPVs circulate in regions that have inadequate vaccine coverage along with an absence of natural infection from circulating wild PV of the same serotype. The strains are of particular concern because they have caused paralytic disease and have a capacity for sustained person-to-person spread similar to wild-type PV.^{106a} The presence of cVDPVs underscores the importance of maintaining excellent surveillance, the need to maintain high vaccine coverage, and the continued risk from suboptimal use of OPV, even in polio-free areas of the world.

Although not as great a concern as cVDPVs, an issue that complicates PV eradication is the demonstrated excretion of iVDPVs, at times for periods of more than a decade. The occurrence of iVDPVs is rare, however, even in immunosuppressed patients. Although both iVDPVs and cVDPVs can occur in the absence of any recombination, recombination has only been observed in the case of iVDPVs with other vaccine PV strains and not with other members of EV-C. This is presumably because of the absence of EV-C co-infections in the tissue supporting the chronic PV infection, in contrast to the frequent recombination observed between vaccine strains that occurs in normal vaccinees. Interestingly, prolonged excretion with PV occurs with viruses derived from OPV, and not with wild PV,²²² perhaps because the greater neurovirulence of wild PV would be expected to lead to a uniformly fatal outcome in immunosuppressed individuals or because individuals with severe immune deficiencies are likely to live in PV-free countries and, therefore, are only exposed to vaccine strains. Currently no evidence indicates that patients with cell-mediated deficiencies are at increased risk for chronic PV infections. Prolonged excretion of PV has not been observed in studies undertaken specifically to look at HIV-infected children and adults.^{147,157}

Included in the VDPV group are ambiguous VDPVs (aVDPVs), in which the source of infection is unknown (e.g., VDPV isolates from environmental sources), no known immunodeficiency is found in the patient, or the isolate is not associated with a PV outbreak. For example, in more than 10,000 vaccine-related isolates studied in WHO Network laboratories in 2011, there were 67 cVDPVs (from 6 recent outbreaks).^{60,427}

Because of the risks evident from VAPP and VDPVs, the WHO has concluded that continued use of OPV following wild PV eradication is incompatible with the ultimate goal of polio eradication. Therefore, sometime after the eradication of wild PV, all use of OPV for routine immunization will stop. This has significant implications for immunization policy decisions and raises two very important basic questions regarding the management of risks: What vaccination policies will be recommended for PV? How will future PV outbreaks or cases be controlled after OPV use has stopped? With regard to the

first question, one option that countries could elect would be to completely stop vaccination for PV. In the absence of wild PV and competing health priorities, this option may be very attractive to many countries, particularly those with limited access to resources. In contrast, concerns about the potential use of PV as a bioterrorism agent means that some countries will continue to vaccinate indefinitely with IPV, as they are doing now. For some countries, particularly middle-income countries, however, the decision about which option to choose may not be simple.

Ideally, it should be possible to describe accurately all of the advantages and disadvantages of choices related to future vaccination policy. It is difficult, however, to estimate and quantitate risks for all populations associated with the cessation of OPV use because of inadequate knowledge about reversion of vaccine strains and viral genetic determinants for neurovirulence and transmissibility. It is also not clear what protective benefits are possible in the absence of high levels of routine IPV use. An attempt to use elements of decision analysis and disease modeling has been made to try to provide better information regarding risk assessments.^{103,393}

Regardless of decisions made about immunization policies, future generations will have an increasing susceptibility to PV as immunization becomes the only source of immunity. For this reason, another key component of activities related to posteradication risk management is the establishment of a global stockpile of vaccine to respond to any outbreak in the future. In most developed countries in temperate climates, IPV has proved very effective in preventing outbreaks in the general population and may remain the vaccine of choice for small outbreaks in the countries. Much remains unknown about the potential for IPV to control PV circulation in developing countries because IPV induces a lower level of mucosal immunity than OPV.¹²⁴ Because OPV is the only vaccine that has ever been demonstrated to stop circulation of PV in developing countries, it will likely remain the vaccine of choice for the global stockpile. If an outbreak does occur, it is reasonable to expect that it will be caused by a single serotype in a specific place or time, prompting the maintenance of monovalent OPV strains in the stockpile. Monovalent OPV strains of all three types are already licensed, and types 1 and 3 are being used for the last stages of polio eradication.⁷⁶ The use of monovalent OPV strains will eliminate the need to introduce undesirable additional strains into the population. Details remain, however, about the response plans and the use of the stockpile that need to be completed. In addition, issues remain about what should be done at the boundaries of the response population. It may be that the process of eliminating OPV may be as complicated and difficult as the process of eradicating the wild virus.

When the eradication program began, it was assumed that the vaccines available at the time were sufficient for the successful achievement of the goal. With the growing knowledge of the risks associated with OPV and the possible difficulties associated with either continuing or stopping its use in the future, hindsight indicates that the availability of additional options would be highly desirable. In the intervening years many new approaches to vaccinology have been developed, raising the possibility of developing new PV vaccines (e.g., genetically engineered PV, noninfectious DNA, or immunogenic peptides). Although some or all of these vaccines might allow protection with greater safety than the present vaccines, no

easy way exists to assess the effectiveness of an untested vaccine against poliomyelitis, given the licensing requirements and demonstration of efficacy. The testing would be expensive and extensive, and passing the test may not ensure universal acceptance of a new intervention. Despite the significant difficulties involving testing these new interventions, it seems appropriate to continue active investigations in this area.¹⁵⁹

The world has endured the crippling effects of PV for millennia, yet the end of these particular viruses is approaching. It is possible that the next edition of this chapter will treat PV quite differently, possibly even as a historic footnote rather than a major focus of public health activities.

PERSPECTIVES

For 25 to 50 years before the identification of acquired immunodeficiency syndrome, much of human virology was focused on PV. With the eradication of poliomyelitis imminent, the picornavirology field is changing and will never be the same again. It is somewhat ironic to realize that, despite the incredible advances in our understanding of the molecular aspects of PV and the availability of extraordinarily powerful molecular tools for studying PV, the eradication of poliomyelitis will become a reality as a result of the use of the Salk and Sabin vaccines, vaccines that were generated empirically in the middle of the last century before the breakthroughs in our understanding of the molecular biology of PV.

But perhaps it is unfair to belittle the achievements of modern techniques in the eradication of PV. Certainly, the tools of molecular biology were and will continue to be important in monitoring and tracking PV and identifying strains; it also may be that new technology and knowledge will make a better PV vaccine. Novel diagnostic methods developed to assist in surveillance of poliomyelitis are likely to aid in the identification of new enteroviruses, provide better and more accurate descriptions of the epidemiology of EV infections, and lead to new anti-EV drugs, nonpolio EV vaccines, and a better understanding of the relationship of EV to acute and chronic human disease.

What new directions will drive the field of picornavirology? Pressure exists to develop new antiviral treatments and vaccines. New antiviral approaches will take advantage of knowledge of virus receptors, structures of capsid and nonstructural proteins, and immunologic features of the disease. New vaccines will be pursued and developed. The ability of EV71 to mount large epidemics and to be a major cause of neurologic disease, especially acute flaccid paralysis, is likely to have already generated special interest with respect to vaccine development. The many diseases that the coxsackieviruses cause also makes this group of viruses of great interest from the point of view of vaccine development. In addition, investigations of coxsackieviral diseases may clarify the pathogenesis of virus-induced autoimmune diseases.

Despite the development of new treatments and vaccines, enteroviruses will still be very much with us, even after the eradication of PV.

ACKNOWLEDGMENTS

We thank Drs. Olen Kew, Tapani Hovi, and Konstantin Chumakov for providing unpublished data.

HISTORY

The common cold has been recognized for millennia, and both the illness and prescribed remedies have been influenced by and engendered a broad body of folklore. In fact, the name of the illness stems from the belief that being chilled causes the illness, a concept that studies using experimental inoculation techniques have been unable to verify.⁵³ In Chinese traditional medicine, colds were considered an illness of wind and cold, and the Roman physician Galen wrote “The white-colored substance (the phlegma) collects mostly... in those who have been chilled in some way”.¹⁴ Through the ages, ideas about pathogenesis have varied widely, and suggestions for common cold cures were creative and occasionally bizarre, but seldom helpful. Enthusiasm for a cure for the common cold remains quite high today; a web-based search yielded 4,120,000 hits in response to the terms “common cold cure.”

In modern times, Kruse in 1914¹³⁹ demonstrated that cell-free filtrates of nasal secretions from affected individuals could transmit colds. In 1930, Dochez et al.⁵⁰ confirmed these findings by transmitting colds to volunteers and apes using filtered nasal secretions that were free of bacteria, indicating a viral etiology. Progress in finding the cause for common colds was accelerated by the establishment of the Common Cold Unit (CCU) by the UK Medical Research Council in 1946.²³⁷ The building was originally a hospital established by Harvard University and the American Red Cross to support Great Britain in World War II, and after the war the building was donated to the British government. At the time one virus was presumed to cause colds, and another to cause influenza.²³⁷ The goals of the CCU, led by Christopher Andrewes and later David Tyrrell, were to identify the common cold virus, its means of transmission, and host characteristics that promoted more severe illness. From 1946 until the unit closed in 1989, more than 20,000 volunteers participated in these studies.

Rhinoviruses were discovered beginning in 1956 by two groups working independently.^{190,198} It was not long before

researchers realized that several families of viruses caused common cold illnesses, and that human rhinovirus (HRV) serotypes were numerous. In 1967, a collaborative program classified the known rhinoviruses into 55 different serotypes,¹ serotypes 56 through 89 were added in 1971,² and the remainder of the classical serotypes were added in 1987.⁸⁸

The development of molecular techniques for detecting HRV in a variety of clinical specimens led to a renewed period of discovery related to HRV classification and epidemiology. Recent findings include the discovery of the genetically distinct HRV-C species viruses that do not grow in standard tissue culture, and additional insights into the role of HRV not only in common colds, but also otitis, sinusitis, lower respiratory infections, asthma, and acute exacerbations of chronic respiratory diseases such as asthma.

Infectious Agent Classification

The human rhinoviruses comprise the HRV-A, HRV-B, and HRV-C species of the *Enterovirus* genus in the *Picornaviridae* family. Classification is based on overt similarities in genome organization, capsid properties, and primary sequence conservation.¹⁸⁵ Viruses are assigned to these species classifications if they share greater than 70% amino acid identity in the P1, 2C, and 3CD regions with other members. Within species, isolates are subdivided into numeric genotypes (Fig. 18.1). For the HRV-A and HRV-B, several historic clinical panels archived by the American Type Culture Collection, were combined and indexed into 101 original HRV types after assessment of antigenic crossreactivity or serotyping in rabbits. HRV-A87 was subsequently reassigned to the *Enterovirus D* (HEV-D68) after reevaluation of genetic, immunogenic, and receptor use (decay-accelerating factor as a receptor) properties.²¹⁰ New HRV isolates, especially for the HRV-C, are now rarely tested for immunogenicity. Type assignments still respect the historic naming system, but rely more heavily on sequence comparisons, primarily of the VP1 protein or VP4/VP2. Strains within a common genotype generally share greater than 12% to 15% aligned amino acid identity in either or both of these regions. Full genome sequencing indicated that some historic types are more closely related than this (e.g., A09 and A95, or A29 and A44), and others such as A45 and A95 defining “clade D” may be sufficiently different as to warrant eventual designation as a fourth species (Fig. 18.1). Because many HRV-Cs are not yet fully sequenced, genotype assignments in this species still rely on comparative VP1 data. Nomenclature conventions for all HRVs cite both the species letter and genotype assignment (e.g., A16, B14, C01) to prevent ambiguity among assigned HRV-A (77 types), HRV-B (25 types), and HRV-C (49 types).

FIGURE 18.1. Circle phylogram relationships for known genotypes of human rhinovirus (HRV)-A, HRV-B, and HRV-C. The tree was calculated with neighbor-joining methods from aligned, full-genome RNA sequences, and rooted with data from human enterovirus (HEV)-A, HEV-B, and HEV-C species (similar to 186). The outer ring ("1" or "2") indicates anticapsid drug group types, if known.⁷ The inner ring shows members of the Major ("M," intercellular adhesion molecule 1 [ICAM-1]) and minor ("m," low-density lipoprotein receptor [LDL-R]) receptor groups. The HRV-C receptor is unknown. Because few HRV-C are fully sequenced, relationships among these genotypes rely on partial VP1 RNA data (lower left). Bootstrap values (percent of 2,000 replicates) are indicated at key nodes.

Physical Characteristics

As enteroviruses, the HRV have genome organizations (Fig. 18.2) and capsid structures (Fig. 18.3) similar to those of polioviruses, coxsackie viruses, and enteric cytopathic human orphan (ECHO) viruses. But unlike other enteroviruses that remain viable at pH 3.0, HRV particles are unstable at pH below 5 to 6. The icosahedral capsid (~30 nm diameter) has 60 copies each, of proteins VP1, VP2, VP3, and VP4, named in order of descending electrophoretic mobility. The protein shell surrounds a densely packed, single-stranded, positive-sense RNA genome of 7079 (C01) to 7233 (B92) bases, a count that does not include the variable length 3' poly(A) tail. Several HRV capsids have been resolved at the atomic level resolution, including A01 (*1r1a*), A02 (*1fpn*), A16 (*1ayn*), B03 (*1rhi*), and B14 (*4hrv*), with multiple structure variants showing

receptor interactions (e.g., A16 with intercellular adhesion molecule 1 [ICAM-1], *1d3e*) or antiviral drug interactions (e.g., A16 with pleconaril, *1c8m*). Like poliovirus, the surfaces of HRV-A&B capsids are dominated by the three largest proteins (Fig. 18.3). VP4 is internal to the structure, centered near the fivefold axis. Around the exterior fivefold plateau, a symmetrical "canyon" provides receptor binding sites and immunogenic surfaces. There are no current structures for an HRV-C, but available sequences indicate significant deletions in the VP1 regions contributing to the fivefold plateau, so it is likely the HRV-C have unique topologies.¹⁶¹ Common to all HRV, the VP1 cores surround a hydrophobic "pocket" or cavity, which can uptake and bind antiviral drugs like pleconaril or other capsid-binding agents. Type-1 long (e.g., B14) or type-2 short (e.g., A16) pocket shapes are defined for most

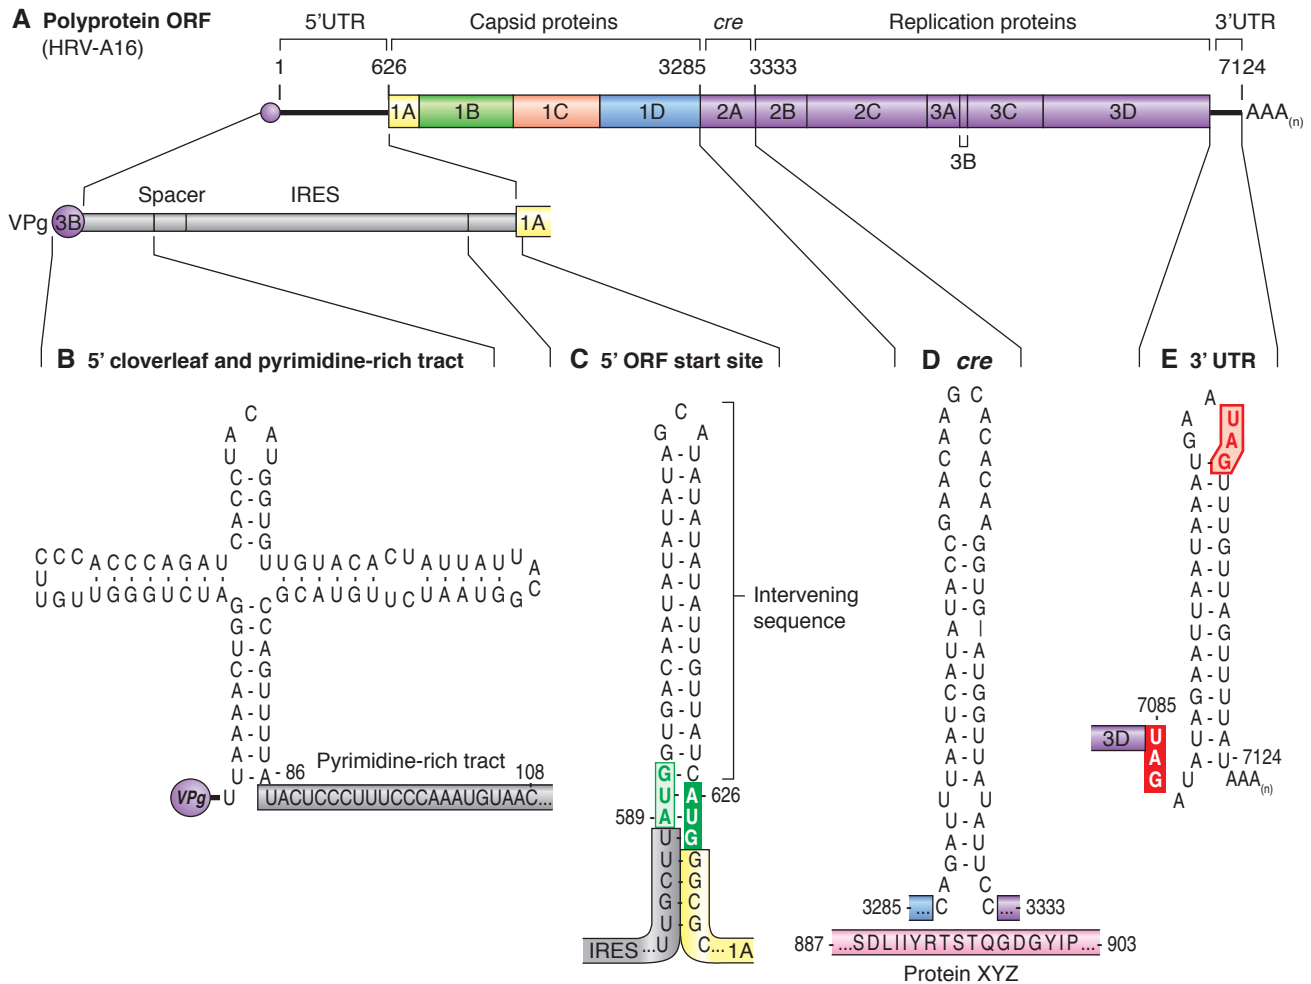

FIGURE 18.2. The genome of an HRV encodes a single polyprotein open reading frame (ORF) (A). Important RNA structural motifs include a 5' cloverleaf (B), ORF start-site stem (C), a *cre* element (D), and 3' stem motif (E).

HRV-A&B and determine whether a virus is susceptible to particular drugs aimed at inhibiting the uncoating process.⁷

The HRV genome is messenger-sense, encoding the polyprotein open reading frame (ORF) and multiple important RNA structural motifs (Fig. 18.2). Adjacent to the 5' cloverleaf, a regulatory feature for translation and replication, each HRV encodes a strain-specific pyrimidine-rich tract that may be involved in suppressing innate immunity triggers.¹⁸⁶ The type-1 internal ribosome entry site (IRES) 3' to this tract, includes a variable-length stem structure pairing the ORF start site (AUG) with an upstream AUG. Unlike poliovirus, intervening sequences between these AUGs are probably not scanned by initiating ribosomes.¹¹⁴ The picornavirus VPg uridylation reaction, required for RNA synthesis, is templated by a special structure called the *cre* (*cis*-acting replication element) whose location varies in every species of picornavirus. For the HRV-A, the *cre* is in the 2A gene.²²⁵ For the HRV-B, the *cre* is in the 2C gene.²²⁵ The HRV-C *cre* has been proposed as one of two sites in the 1B gene.^{37,186,225} Neither has been confirmed experimentally. The short, 3' untranslated sequences (untranslated regions, UTRs) are of highly variable sequence. Invariably, they configure as an inclusive stem motif display-

ing at least one bogus termination codon in the terminal loop. This codon may be in-frame or out-of-frame with the authentic ORF stop site, and has been proposed to play a role in the recruitment of translation termination factors.¹⁸⁶

Pathogenesis and Pathology

Entry into the Host

The primary portal of entry for HRV infections is through inoculation of either the eyes or nose. Studies of seronegative infected volunteers have shown that very low doses of HRV, substantially less than the amount needed to infect cells *in vitro* (one tissue culture infectious dose₅₀ [TCID₅₀]), can cause infection when introduced via the conjunctiva or nasal mucosa.⁴¹ In contrast, approximately 10,000 times as much virus is needed to cause productive infection when the inoculation site is the tongue or external nares.⁴¹

Site of Primary Replication

The primary site of infection is the airway epithelium. In studies of airway tissues from either natural or experimentally induced colds, detection of viral protein or RNA is largely confined to the epithelial layer, along with an occasional cell in

FIGURE 18.3. Capsid structure of a human rhinovirus (HRV) (**A**), illustrates the icosahedral surface topography of VP1, VP2 and VP3 proteins. The VP4 is internal to the capsid (**B**). Type 1 and type 2 antiviral capsid drugs bind in a pocket, internal to VP1.

the subepithelial layer (Fig. 18.4).^{11,23,175} Highly differentiated epithelial cells grown at air–liquid interface are more resistant to HRV infection compared to undifferentiated monolayers of cells.¹⁵⁴ In addition, mechanical damage to well-differentiated cells significantly enhances viral replication *in vitro*.¹¹⁶ These findings suggest that the epithelial barrier function is an important contributor to the resistance against HRV infections. In addition, differentiation of epithelial cells in tissue culture in the presence of interleukin-13 (IL-13) *in vitro* causes increased numbers of goblet cells and greater HRV replication *in vitro*, suggesting that HRV replication is increased in goblet cells.¹⁴³

Spread

For years it was assumed that HRV infection was confined to the upper airway and did not affect the chest except under unusual circumstances. In fact, one of the breakthroughs that led to successful propagation of HRV in cell culture was the discovery that this virus replicated best at 33°C to 35°C. It was assumed that the lower airways were at core temperature (37°C), and this characteristic was thought to limit HRV replication to the cooler upper airways. Contrary to these initial assumptions, direct measurements in the lower airways have shown that large- and medium-sized airways are at the ideal temperature for HRV replication (Fig. 18.5).¹⁶³ In addition, cultured lower airway epithelial cells support HRV replication *in vitro* at least as well, and perhaps even better, than cells derived from the upper airways.^{155,174}

Following experimental inoculation of the upper airway, HRV has been detected in the lower airways of individuals with a variety of techniques. Secretions from the lower airways sampled by bronchoscopy and bronchial lavage were analyzed by reverse transcriptase–polymerase chain reaction (RT-PCR), and more than half of the lower airway specimens tested positive for HRV.^{73,214} These findings were extended by subsequent

FIGURE 18.4. Human rhinovirus (HRV)-C15 replication within epithelial cells in sinus organ culture. **A:** Sinus tissue in organ culture was inoculated with HRV-C15 (center and right) or medium alone (left), and whole mounts of the tissue were analyzed for HRV-C15 RNA by *in situ* hybridization (purple stain). Scale bars, 1 mm. **B:** Higher magnification view of the areas boxed in panel **a**, showing uninfected cells (left) or cells containing viral RNA (center and right). Scale bars, 0.15 mm. **C:** Sections of mock (left) or HRV-C infected (center and right) sinus tissue. Right panel is counterstained with eosin (pink). Scale bars, 15 μ m. (From Bochkov YA, Palmenberg AC, Lee WM, et al. Molecular modeling, organ culture and reverse genetics for the emerging respiratory pathogen human rhinovirus C. *Nat Med* 2011;17: 627–632; with permission.)

FIGURE 18.5. Temperatures in the lower airways are ideal for human rhinovirus (HRV) replication. Direct measurements of temperature in lower airways have been recorded at measured distances from the nares using a bronchoscope equipped with a small thermistor.¹⁶³ Even when the inspired air is at room temperature (26.7°C), airway temperatures in the medium and large airways are in the range of 33°C to 35°C. In contrast, small airway temperatures approach core temperature (37°C). insp, inspiration; exp, expiration.

studies demonstrating the presence of intracellular HRV RNA and protein using *in situ* hybridization and immunohistochemistry, respectively.^{175,187} Analysis of sputum has been used to provide an estimate of the quantity and kinetics of viral shedding from the large lower airways. After experimental inoculation of seronegative volunteers, viral shedding from the upper airway peaks 2 to 4 days later. Analysis of sputum specimens 3, 7, and 14 days after inoculation revealed that peak levels of virus in the sputum occurred 3 to 7 days after inoculation.¹⁷⁵ In addition, about half of the volunteers had viral shedding in the sputum that was equal to or exceeded that found in the nasal secretions. Notably, only small amounts of virus were detected in bronchial lavage specimens, which originate from distal airways and alveoli.¹⁷⁵ These findings suggest that HRV replication is greatest in the upper airway in most individuals, and that high-level replication can also occur in the large- and medium-sized airways.

Data from natural cold studies also provide evidence of lower airway infections with HRV. Viral recovery from sputum during colds can exceed that obtained from upper airway samples.¹⁰⁶ In epidemiologic studies, HRV is frequently detected in children who are hospitalized with wheezing illnesses and in infants with pneumonia.^{166,167,193} In wheezing infants, HRV has been detected in lower airway biopsies, and HRV detection was associated with reduced lung function in these infants.¹⁵⁸ In children with tracheostomies, samples of nasal mucus can be obtained directly from the lower airway without contamination from nasal secretions, and HRV detection rates from upper versus lower airway specimens are similar.²¹⁷

In addition to infecting the nasopharynx, conjunctiva, and lower airways, HRV has also been recovered in specimens obtained from the middle ear and sinuses.^{29,117,194,196} The respiratory epithelium in each of these two locations is contiguous with that of the nasopharynx, and the virus presumably spreads

via local extension. Rhinovirus viremia has been detected in infected children by PCR but not by recovery of infectious virus,²⁶⁰ and a study of experimentally infected adults showed no evidence of circulating HRV RNA.⁴⁵ Therefore, systemic infections do not occur in immune competent individuals. HRV are inactivated at pH less than 6, thus preventing swallowed virus from replicating in the gastrointestinal tract.

Cell and Tissue Tropism

Biopsies of the upper airway from infected volunteers show a patchy pattern of infection with small foci of infected cells.^{10,195,256} Point cultures of the airway have demonstrated high levels of HRV shedding in the nasopharynx and especially in the adenoidal region. Examination of biopsies obtained during experimentally induced colds suggest that a specific type of nonciliated adenoidal epithelial cell, resembling the intestinal M cell, expresses high levels of ICAM-1 and supports high-level viral replication.²⁵⁵ It is possible that these cells play a sentinel role in the detection of viral respiratory infections.

The receptors for HRV are also expressed by airway cells other than epithelial cells. Besides epithelial cells, HRV can bind to macrophages, monocytes, eosinophils, and fibroblasts.^{72,75,90} Macrophages and monocytes are good sources of type I and type III interferons,^{131,136} which may explain why there is little or no HRV replication in these cells. Airway fibroblasts⁷⁵ and possibly smooth muscle cells¹⁴⁰ support HRV replication in tissue culture, but it has not been established whether these cells, which are located several cell layers under the epithelial surface, are infected *in vivo*.

RECEPTORS

All HRV-A&B use ICAM-1 (88 “major” types) or alternatively, low-density lipoprotein receptor (LDL-R, 11 “minor” types) for recognition and attachment to cells.^{78,243} In addition, the major group virus HRV-A89 binds to heparan sulfate in the absence of ICAM-1.²⁴² The external cellular receptor(s) used by the HRV-C are most certainly different but yet to be identified.^{23,161} Studies utilizing atomic force spectroscopy indicate that after initial HRV binding, multiple receptors are rapidly recruited (within 200 ms).²⁰⁵

SPECIES TROPISM

Rhinoviruses primarily infect humans. Chimpanzees can be infected, but although viral shedding can be detected, there are few or no signs or symptoms of illness.¹⁰⁸ HRV replication in rabbit smooth muscle cells has been reported by a single group.⁸⁶ HRV do not bind to murine ICAM-1, but can bind to murine LDL-R.²⁶¹ Accordingly, minor group viruses can replicate in murine epithelial cells,^{24,236} and strains have been selected for this property by serial passage in murine cell lines.^{17,91} In addition, epithelial cells from transgenic mice engineered to express human ICAM-1 support replication of major group viruses.¹⁷

The demonstration that HRV can grow in murine epithelial cells has led to the development of murine models of HRV infection.^{17,24,178,180,236} Several features of these models resemble infection of the human, including replication in the respiratory epithelium, induction of type I interferons and neutrophil chemokines, and neutrophilic airway inflammation.^{17,180} In addition, HRV infection of mice increases inflammation in response to allergen exposure, suggesting that these models could be informative for asthma.¹⁷ Limitations of the models include the requirement of a large inoculating dose,

and short duration (<24 hours) of significant viral replication and shedding. A second rodent model of picornavirus respiratory infection was developed using a genetically altered strain of Mengovirus, a natural mouse pathogen that causes a polio-like syndrome.²⁰⁶ Intranasal inoculation of rats with attenuated Mengovirus causes infection of the airway epithelium with similarities to HRV infections in humans. The ability to investigate HRV host–cell interactions *in vivo* using the genetic tools available in rodent models should yield important new insights into the pathogenesis of infection in humans.

Immune Response

IMMUNOHISTOCHEMISTRY

HRV infections produce relatively little cytopathology. Findings on biopsy during the peak of the illness include tissue edema and a sparse infiltration of neutrophils and mononuclear cells.^{253,254} The relative lack of pathology together with the small number of infected cells suggests that the immune response to HRV rather than direct virus-induced injury contributes most to respiratory symptoms.⁹⁷

MEDIATORS OF INFLAMMATION

HRV infection induced a variety of proinflammatory cytokines and mediators (Table 18.1). Most of these factors are present in peak concentrations during the acute cold, and correlate with illness severity and viral shedding.¹⁶ There is only circumstantial evidence that these immune mediators contribute to the pathogenesis of cold signs and symptoms, and the specific roles for most of these factors have yet to be defined. Kinins, leukotrienes, and histamine are of special interest due to their effects on vasodilation and edema, which are prominent findings during acute colds.^{110,262} HRV infection of volunteers with asthma induced increased mRNA and activity of human

kallikrein, a critical enzyme for the release of kinins, in the lower airways.³³ These mediators can also cause smooth muscle contraction as well as edema, and thus could promote airway obstruction in patients with asthma. Notably, common colds have little effect on concentrations of histamine in the nose,⁶¹ and second-generation antihistamines (which are specific H1-receptor antagonists), have no effect on cold symptoms.¹⁷⁶ Leukotrienes (LTs) are overproduced during viral respiratory infections,⁷⁰ but the cystinyl leukotriene receptor antagonist montelukast did not affect cold symptoms in experimentally infected volunteers.¹³⁴ In addition, administration of LTB₄ to the nose before experimental inoculation had no significant effects on either viral replication or symptoms.²⁵¹ Kinins are increased early in the course of a cold,²⁰⁰ but testing of their role in pathogenesis awaits the development of safe and effective kinin inhibitors. HRV-induced cytokines may also promote vascular permeability; experiments conducted *in vitro* demonstrate that tumor necrosis factor α (TNF- α), IL-1 β , and IFN- γ can each increase vascular permeability.²¹² Analysis of nasal secretions after experimental inoculation demonstrates that the thin rhinorrhea during the early stages of a cold contains serum proteins (e.g., immunoglobulin [IgG], albumin), and as the cold progresses the composition shifts to mucin proteins.^{110,262} This progression suggests that the pathophysiology of rhinorrhea is time-dependent, and shifts from vascular leakage initially to local secretion of mucus during the mid to latter stages of a cold.

EPITHELIUM

The airway epithelium is the first line of defense against HRV infections. Mucins, antimicrobial peptides, and surfactant proteins in the mucous layer nonspecifically deter infection.¹⁰³ In addition, well-differentiated epithelial cells are relatively

resistant to HRV infection.¹⁵⁴ The epithelium may serve as a barrier against HRV infection; HRV replication is enhanced when apical cells of well-differentiated epithelial cell cultures are either damaged or stripped away.¹¹⁶ This property may help to explain how exposure to factors such as pollutants and allergic inflammation that can damage epithelium also increase the risk and/or severity of HRV illnesses. HRV infection itself can disrupt the barrier function of the epithelium,²⁰⁷ which may contribute to synergistic effects with bacteria, allergens, or irritants.

In addition to being the principal host cells for HRV infections, airway epithelial cells initiate antiviral and proinflammatory immune responses (Fig. 18.6). Attachment of HRV to ICAM-1 activates signaling cascades that lead to the

activation of chemokine genes such as *CXCL10*.^{69,136} Once HRV particles uncoat in the endosome, the release of single-stranded RNA activates additional innate immune sensors. These include toll-like receptors (TLRs) (e.g., TLR-3, TLR-7) that are expressed on endosomal membranes, and the double-stranded RNA-dependent protein kinase (PKR) and RNA helicases (retinoic acid-induced gene I [RIG-I] and melanoma-differentiation-associated gene-5 [MDA-5]). MDA-5 binds to double-stranded RNA that is formed during the replication process, and appears to be an important contributor to anti-HRV IFN responses.^{220,244} The role of RIG-I, which binds to the 5' triphosphate motif and longer stretches of double-stranded RNA,¹⁹ is more controversial. One recent *in vitro* study found that TLR-3 was constitutively expressed on airway

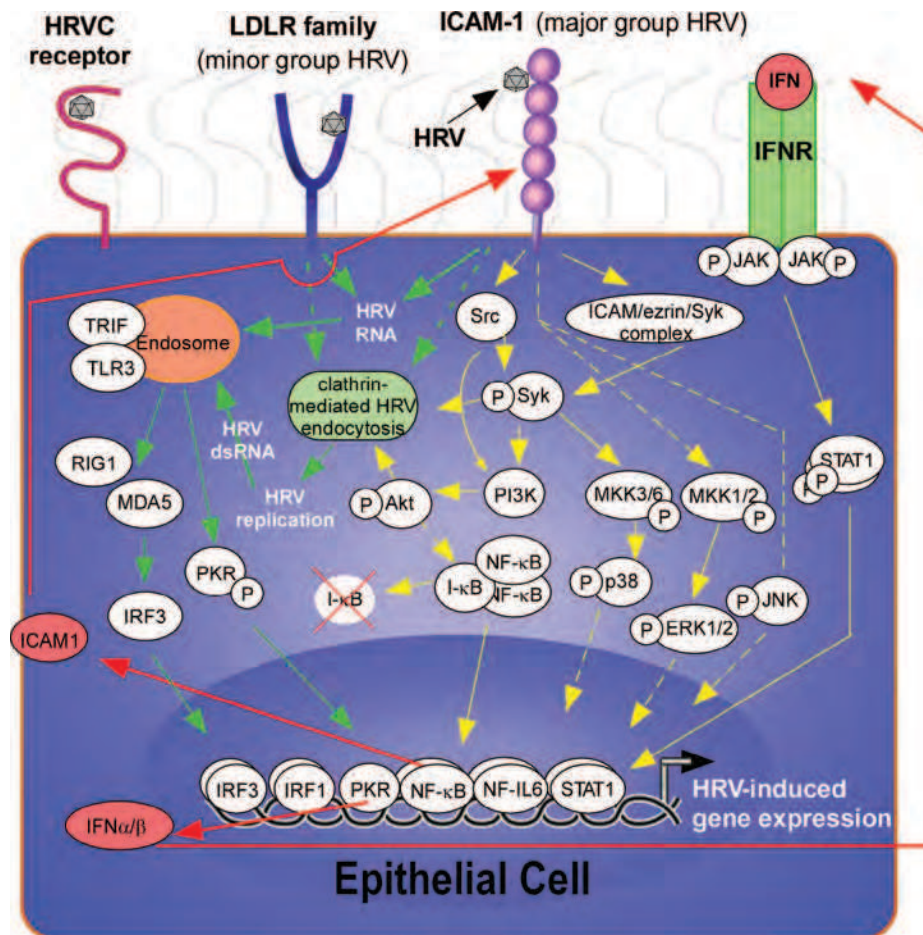

FIGURE 18.6. Airway epithelial cells initiate the immune response to human rhinovirus (HRV). Major group HRV binds to intercellular adhesion molecule 1 (ICAM-1) and minor group HRV binds to low-density lipoprotein receptors (LDL-Rs) on the surface of cells, such as epithelial cells and leukocytes, that would be abundant in the airway, to induce downstream signaling. The receptor and signaling pathways induced by HRV-C types has yet to be elucidated. Upon ligation of HRV to surface receptors on epithelial cells, direct uncoating of viral RNA or clathrin-mediated endocytosis leads to the release/replication of HRV RNA into the cytoplasm. This viral RNA is detected by endosomal receptors, such as toll-like receptor 3 (TLR-3), to propagate downstream signaling and induction of gene expression, including the production of interferons (IFNs) that can exert an autocrine/paracrine effect by binding to IFN receptors and triggering a janus kinase (JAK)-signal transducers and activators of transcription (STAT) signaling cascade. Replication-independent signaling is also induced upon HRV infection, and includes the activation of Src, Syk, and mitogen-activated protein kinase (MAPK) signaling cascades. Yellow solid lines, data to support link; dashed lines, indirectly connected (may have signaling molecules in between); red lines, signaling induced by product of HRV-induced gene transcription; green lines, replication-dependent signaling. (From Gavala ML, Bertics PJ, Gern JE. Rhinoviruses, allergic inflammation, and asthma. *Immunol Rev* 2011;242:69–90, with permission.)

epithelial cells, and activation of TLR-3 led to induction of RIG-I and MDA-5.²²⁰ Subsequently, all three of these molecules contributed to upregulation of innate IFN responses to HRV infection.

Engagement of cell surface receptors and RNA-sensing molecules leads to activation of several signaling cascades, including nuclear factor kappa B (NF- κ B), janus kinase (JAK)-signal transducers and activators of transcription (STAT) pathways, and mitogen-activated protein kinases (MAPKs).^{60,87,99,132,136,144,146,179,180,245,263} Viral proteases can also contribute to cell activation; the 3C protease cleaves the transcription factor organic cation transporter-1 (OCT-1),⁶ which negatively regulates CXCL8 (interleukin-8) transcription. The net result of these actions is activation of viral sensing and antiviral effector pathways, IFNs, and a variety of proinflammatory cytokines and chemokines.^{22,31,202} Type I IFNs inhibit HRV replication by inducing multiple antiviral pathways, and also prime epithelial cells to synthesize chemokines such as CXCL10.^{6,137} IFN- γ has several effects on viral replication and inflammatory responses. It is a potent inducer of ICAM-1¹³⁵ and soluble ICAM-1,²⁵⁰ and effects on viral replication in cultured epithelial cells depend on experimental conditions. In addition to affecting viral receptor expression, IFN- γ also enhances the HRV-induced secretion of chemokines such as CCL5.¹³⁵ HRV-induced chemokines from epithelial cells and other sources attract a variety of cells into the airway, including dendritic cells, monocytes, macrophages, epithelial cells, and lymphocytes (Table 18.1). The ensuing cellular response promotes antiviral effects and killing of infected cells, but also increases inflammation that contributes to the pathophysiology of illness.

CELLULAR IMMUNE RESPONSES

Macrophages are the principal cells in lower airway secretions, and it is likely that these cells are important contributors to the innate antiviral response. Considering that little to no replication of HRV has been observed in airway macrophages or blood monocytes,^{72,146} the signaling pathways could differ from those in epithelial cells, in which viral replication processes provide potent innate immune stimulation. As in epithelial cells, HRV activate NF- κ B and STAT-1-dependent pathways. For example, HRV-induced secretion of CCL2 involves activation of NF- κ B and phosphorylation of activating transcription factor-2 (ATF-2).⁸⁷ Furthermore, HRV-A16 induces STAT-1 tyrosine phosphorylation and IFN- α release in monocytes.¹³⁶ NF- κ B activation, but not the p38 MAPK, has been reported to be involved in HRV-mediated TNF- α release by monocytes.¹⁴⁶

Macrophages are important sources of cytokines (e.g., TNF- α), chemokines (e.g., CXCL8 [IL-8], CXCL10 [IP-10], CCL2 [MCP-1]), and type I and type III IFNs during HRV infections.^{87,127,131,146} Although epithelial cells and macrophages in isolation can both respond to HRV infection, co-culture of these cells leads to synergistic enhancement of selected chemokines such as CXCL10, and this synergy has been linked to macrophage secretion of IFN- α .¹³⁷ Airway dendritic cells are interdigitated into the epithelium, and as major producers of type I IFNs²¹⁵ they are likely to be important in orchestrating the early innate response to HRV infection.

Neutrophils are the most numerous cells in airway secretions during an HRV cold.^{118,231,254} Experiments conducted after experimental HRV inoculation demonstrate that granulocyte-colony stimulating factor (G-CSF) is secreted into the

nasal secretions within 24 hours, followed closely by increased in circulating G-CSF that can boost the production of neutrophil precursors in the bone marrow.¹¹⁸ Neutrophils increase in the blood 1 to 2 days after inoculation, and are then recruited to upper and lower airway secretions. Neutrophilic inflammation correlates with respiratory symptoms, and it is suspected that these cells have both antiviral and proinflammatory effects during the cold.^{16,79,118,230,231} The P2 \times ₇ receptor is a cation channel expressed on epithelial cells and leukocytes that is activated after binding ATP, and can therefore initiate inflammatory responses secondary to virus-induced cellular damage and other stimuli that release ATP. In volunteers who were experimentally inoculated with HRV, P2 \times ₇ pore activity measured in blood cells correlated with the influx of neutrophils into upper airway secretions during the acute cold.⁴⁶

Lymphocyte numbers dip briefly in the blood during an acute cold, and rise in nasal secretions, but to a lesser extent than neutrophils.^{151,152} T-cell responses are critical for resolution of HRV infections, as indicated by reports of prolonged and sometimes severe symptoms in immunosuppressed individuals or those with primary immune deficiencies.^{68,112} T-cell responses can be directed at either serotype-specific or shared antigens.⁷¹ Vigorous HRV-specific proliferative responses in seronegative volunteers at baseline were associated with milder clinical symptoms, suggesting a potential role for lymphocytes in the initial antiviral response.¹⁸⁸

ROLE OF ANTIBODY

Antibody responses can be detected as early as 7 to 14 days following experimental inoculation, and it is likely that both IgG and IgA responses to HRV contribute to protection from reinfection.^{41,66,192} Preexisting antibody reduces the rates of HRV infection and illness. Studies of natural infections among families found that the infection rate for individuals with serum antibody was half that of antibody-negative subjects,^{41,66} and similar findings were reported in trials of experimental inoculation.^{4,28} In addition to protection associated with antibody responses to a homotypic virus, serial challenges with heterotypic virus also produced a reduced frequency of infection, suggesting either the presence of cross-reacting antibodies or protective mechanisms not involving antibody.⁶⁵

Release from Host and Mode of Transmission

The transmission of HRV infections has been the subject of a number of creative and innovative studies. Dick and colleagues⁴⁹ compared the HRV transmission rates from experimentally infected donors to seronegative recipients under controlled conditions. Some volunteers wore arm restraints or plastic collars designed to prevent hand to face contact; rates of transmission were similar for these volunteers compared to those with no restraints. These results are in agreement with observations that a related virus (coxsackievirus A21) could be spread by aerosol droplets.⁴⁰ On the other hand, Dr. Jack Gwaltney and colleagues⁸¹ found that contact with coffee cups or plastic tiles contaminated with wet secretions could transmit HRV infections to volunteers who handled the fomites and then rubbed their eyes and nares with their fingertips. In addition, transmission of HRV can be inhibited by cleaning the hands with virucidal solutions, or by the use of virucidal tissues when blowing the nose.⁴⁸ Notably, items with dried secretions contain little virus and were not able to transmit colds. Collectively, these

findings indicate that HRV can be transmitted by either aerosol or fomites, and that the predominant mode of transmission may depend on age, personal hygiene, and degree of viral shedding.

Virulence

With the very large number of HRV serotypes and genotypes, it is likely that some are more or less virulent. Early studies relying on tissue culture documented that at least 20 different HRV serotypes could cause wheezing illnesses. Larger studies using molecular diagnostics indicate that HRV-C infections appear to be overrepresented in more severe illnesses, including wheezing in infants and young children,⁸ and acute exacerbations of childhood asthma.²⁰ There is also a single report of HRV-C recovery from pericardial fluid in a child with signs and symptoms of systemic infection.²²⁸ Given that prevailing HRV strains change almost completely, additional studies include community surveillance over multiple seasons to definitively establish whether HRV-C are more virulent, and whether there are selected types of HRV-A and HRV-B with the same properties.

Persistence

Several studies have observed that following acute HRV infections, virus can sometimes be detected for weeks,^{120,259} and this has led to speculation that HRV might cause chronic infection. In fact, studies that have performed HRV typing following either natural or experimentally induced infections provide definitive evidence that most HRV infections are cleared after 1 to 2 weeks.^{45,184} Prolonged detection of HRV is usually explained by serial infections with different HRV types, and shedding of a single virus for four weeks or longer is a rare event in immunocompetent individuals.¹¹⁹ In contrast, immunodeficient or immunocompromised patients can shed the same HRV type for prolonged periods, and can have more severe illnesses.^{68,112,130}

Detection of HRV in the absence of respiratory symptoms is common, and rates of asymptomatic infection in infants are especially high (25% to 44%).^{141,150,240} This could be a reflection of the age-related increased susceptibility to all HRV infections (symptomatic or not), but it is also true that mild symptoms (e.g., sore throat) may not be recognized in infants. In surveillance studies of infants, 10% to 20% of these “asymptomatic infections” reflect viral shedding follow-

ing recovery from a cold, or a prodromal period just before the onset of respiratory illness.^{109,120,240,257} Studies that have performed serial sampling of respiratory secretions have found no evidence that HRV establishes a “carrier state” characterized by persistent low-level viral shedding.^{119,184,191} The quantity of viral shedding is not a good differentiator of symptomatic versus asymptomatic infection.¹⁹¹ Notably, both symptomatic and asymptomatic infections can elicit immune responses.¹²³ When considered together, these findings indicate that detection of HRV shedding by culture or PCR is indicative of infection, and that asymptomatic infections are common and need to be considered in epidemiologic studies linking infection to illness outcomes.

Epidemiology

Age

HRV infections are most common in infants and young children. There is evidence that infection rates are somewhat lower in the first 6 months of life, and then rates are relatively high throughout infancy and early childhood.^{18,47,66,105,113,238} Among young adults, infection rates are greater in mothers and women of similar age compared to men. In older adults, this relationship is reversed and illness rates are higher in men.⁸²

Morbidity

HRV cause a broad spectrum of illness including asymptomatic infections, common colds, and other upper respiratory illnesses, bronchitis and wheezing illnesses, and lower respiratory tract infections including bronchiolitis, bronchitis, wheezing, and pneumonia (Fig. 18.7). The wide range of illness suggests that there are a number of factors related to the virus, the host, and the environment that contribute to the severity of illness. With 100 traditional serotypes and more than 40 HRV-C types, it is likely that there are species or strain-specific patterns of virulence. The C viruses appear to be overrepresented in studies of hospitalized children^{51,89,145,148,153,156,162,166} and acute exacerbations of asthma,²⁰ but longitudinal data including large numbers of HRV illnesses of varying severity are needed to confirm these findings.

Most of the morbidity associated with HRV infections is in high-risk groups: infants, the elderly, immunocompromised individuals, and patients with chronic respiratory diseases such as asthma,^{39,129,182} chronic obstructive lung disease,²⁵⁸ and cystic

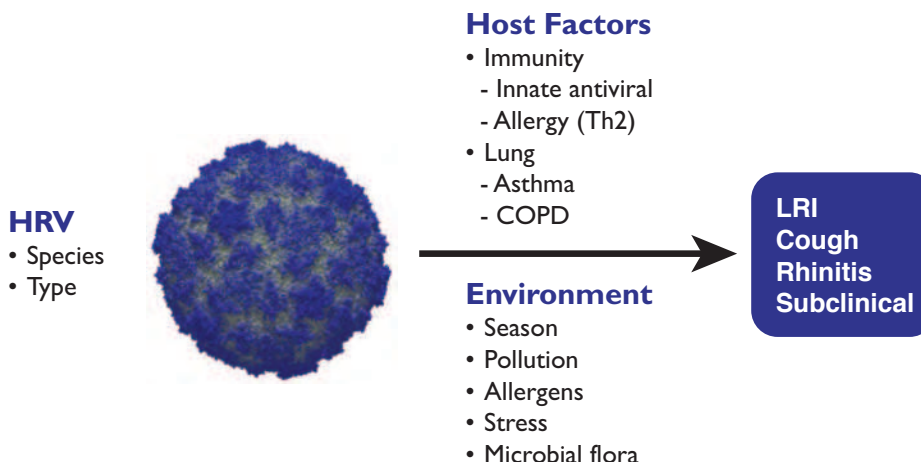

FIGURE 18.7. The spectrum of human rhinovirus (HRV) illness (see text).

FIGURE 18.8. Age-related hospitalization rates for rhinovirus lower respiratory infection. (From Miller EK, Lu X, Erdman DD, et al. Rhinovirus-associated hospitalizations in young children. *J Infect Dis* 2007;195:773–781, with permission.)

fibrosis.^{35,222,249} Risk factors for HRV wheezing illnesses in early life include maternal atopy, a history of previous wheezing episodes, and increased airway resistance on infant lung function tests.^{122,168,224,239} Population-based hospitalization rates were calculated for children hospitalized in Rochester, New York, and Nashville, Tennessee (Fig. 18.8); one major children's hospital serves the population in each of these communities.¹⁶⁷ Young age and a history of previous asthma or wheezing were two risk factors for HRV lower respiratory illness. Finally, several studies indicate that allergic children are especially likely to develop acute wheezing illnesses with HRV infections.^{100,184,204}

Environmental factors that contribute to the severity of HRV illness include tobacco smoke and other pollutants.^{57,181,241} Several studies have provided evidence that stress increases the severity of natural and experimentally induced colds.^{34,226} Seasonal influences have been linked to cold prevalence, and likely also affect severity of illness. Notably, vitamin D status has been shown to be associated with the prevalence of upper respiratory illnesses, although specific links to HRV infections have not been established.⁷⁶

HRV infections have been closely linked to the inception and exacerbation of asthma (Fig. 18.9). Many respiratory viruses can cause wheezing episodes in infancy, and low lung function and environmental exposures such as tobacco smoke increase the risk for wheeze. Most children recover fully, but a subset subsequently develop recurrent wheezing illnesses and asthma. Wheezing with HRV infections during infancy and early childhood is one of the strongest indicators of risk for subsequent childhood asthma, especially in those individuals who develop allergen-specific IgE (allergic sensitization) at an early age.^{113,138,142} The causality of this relationship is uncertain. Once asthma has become established, viral respiratory illnesses (most commonly caused by HRV) are the most com-

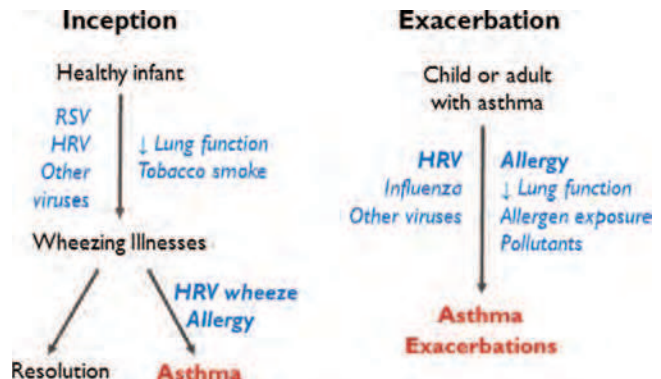

FIGURE 18.9. Human rhinovirus (HRV) infections and asthma (see text).

mon trigger for acute exacerbations of asthma. The relationship between HRV infections and acute asthma is especially close in childhood; HRV infection is detected in up to 85% of asthma exacerbations in children compared to about half of exacerbations in adults.^{13,100,101,129,182,184} There is a remarkable similarity in the seasonal patterns of HRV infections and exacerbations of asthma, especially in school-aged children in whom hospitalizations due to asthma have a strong fall and spring preponderance year after year.^{125,126,128} Even so, the use of routine monitoring of respiratory secretions for HRV in children with asthma demonstrates that only a subset of HRV infections cause exacerbations.¹⁸⁴ Children with respiratory allergies are at greatest risk for virus-induced wheezing, and other risk factors include exposure to allergens or pollutants, obstructive changes on lung function testing, and failure to use asthma-control medications.^{30,57,77,125,177,241}

Origin and Spread of HRV Infections

In general, transmission of HRV infections is relatively inefficient. Children have the highest rates of HRV illnesses, and also appear to transmit infections most effectively. In family surveillance studies, transmission from children to other children and adults was much more common than transmission from adult to children or other adults.^{98,191} Epidemics with HRV are uncommon, although they have been reported to occur associated with “flu-like” illnesses in nursing homes.^{62,102} Secondary attack rates within families vary between 30% and 70%.

Conditions that affect transmission of HRV infections were identified in studies of experimentally inoculated HRV “donors” and seronegative adult “recipients”. Short-term (15 minute to 3 hours) contact led to transmission rates of less than 10%, even in the presence of loud vocalization, card playing, and kissing.^{41,83} Higher rates of transmission were observed among donor and recipient married couples (38% transmission rate),⁴² and in a crowded research hut in Antarctica (88% to 100% transmission rate).¹⁰⁴ Transmission of natural colds in a more spacious Antarctic hut occurred at a relatively low rate (~1% per day among 200 inhabitants), and it was notable that transmission rates were similar among long-term residents and recent arrivals to the research station.²⁴⁸ In clinical studies that reproduced the close contact of the studies in Antarctica, the best predictor of transmission of a cold from a donor to a seronegative recipient, was the duration of exposure

FIGURE 18.10. Relationship between the exposure and transmission of human rhinovirus (HRV)-A16. A series of experiments (A–F) was conducted in which donors with severe experimentally induced colds (HRV-A16) were housed with seronegative recipients for varying lengths of time. The groups were housed in a clinical research unit from 5 to 79 hours, and samples of nasal lavage fluid were obtained for 10 days and analyzed for viral shedding. One donor-hour of exposure (DHE) was defined as exposure to one infected donor for 1 hour. There was a straight-line relationship between the logarithm of DHE and the risk of HRV transmission. (From Meschievitz CK, Schultz SB, Dick EC. A model for obtaining predictable natural transmission of rhinoviruses in human volunteers. *J Infect Dis* 1984;150:195–201, with permission.)

(Fig. 18.10).¹⁶⁵ In general, factors that promote transmission include young age, symptomatic illness, crowding, high-level viral shedding from the index case, and seronegativity of the recipient.^{124,172}

Prevalence and Seroepidemiology

HRV infections occur year round, with increased prevalence in the fall and spring (Fig. 18.11).^{66,157,171,257} The increased prevalence in the fall has led to speculation that school-based

FIGURE 18.11. Seasonality of human rhinovirus (HRV) infections. Between October 1994 and November 1995, 200 young adults (mean age 24 years, mostly university students) were followed for the occurrence of common cold symptoms. Nasopharyngeal aspirates obtained during periods of illness were analyzed by polymerase chain reaction (PCR) for rhinoviruses and other respiratory viruses. The graph depicts the monthly occurrence of upper respiratory illnesses, and illnesses that were positive for HRV by PCR-based diagnostics are indicated by the blue bars. Data from.¹⁵⁷

transmission among children may drive this trend.¹²⁶ HRV infections continue during the wintertime, but account for less than 50% of infections during this period of time due to the plethora of other respiratory viruses found at this time of year. The prevalence of HRV infections increases again in the spring, and is lowest in the summertime. Overall, HRV infections account for about half of common cold infections over the entire year, and more than 80% of infections during peak seasons in the spring and fall HRV.

More than 20 types of HRV can circulate within a community at any given period of time, and the composition of HRV types in a single community changes almost completely from season to season and year to year.^{170,184} Some studies have reported species-specific patterns of HRV prevalence,^{166,184} but because the range of viruses differs markedly with season and location, several years of data will be necessary to confirm these patterns.

Serologic responses to the various rhinovirus types can be detected in infants, and the number of serotypes to which antibodies are present increased throughout childhood and adolescence.^{80,172} The prevalence of serotype-specific antibodies peaks in young adults (mean percent positive = 60%), and remains at 40% to 50% throughout adulthood. Type-specific antibody in the same individual can persist at relatively stable levels for years.²²⁹

Epidemiologic studies of HRV prevalence are best conducted with molecular diagnostics because of difficulties in culturing these viruses (especially the C species viruses). Serologic tests can be performed for culturable viruses, but due to the large number of serotypes, antibody responses are measured mainly in experimental inoculation studies performed with a single serotype.^{84,234}

Genetic Diversity of Virus

As might be predicted from the original HRV typing system, a large degree of sequence diversity among the HRVs manifests as amino acid changes in capsid surface regions mapped as neutralizing immunogenic epitopes (Nims). Completion of the full cohort of HRV-A&B sequences identified extensive

evidence for historic recombination among species clades (Fig. 18.12). Surprisingly, these recombinants had not exchanged capsid regions. The most common trades included the 5' UTR, primarily upstream of the IRES, or less frequently, fragments from P2-P3 regions. Recent HRV sequencing from multiple field isolates confirmed this idea, showing clearly

FIGURE 18.12. Recombinant origins for many human rhinovirus (HRV). A&B were uncovered by genome sequencing.¹⁸⁶ Parents (solid boxes) or progeny (two-color boxes) are founders of many clades.

that the HRV-A and HRV-C frequently recombine, and when they do, they exchange not the expected capsid Nims, but 5' UTR regions, including the pyrimidine-rich tracts, and their respective 2A protease genes.^{107,164} Comparative 2A work is underway to document why evolution apparently favors these particular recombinants. Possibly, divergent protease specificities may help these viruses regulate the overall cell response to infection.

Picornavirus polymerases have a high error rate, estimated at 10^{-3} to 10^{-4} errors/nucleotide/cycle of replication. As a result, HRV types exist as quasispecies populations. Analysis of 34 full HRV sequences of prototype strains demonstrated that the HRV genome as a whole is under purifying selective pressure, with focal areas of diversifying pressure at antigenic sites in the structural genes, and in the 3C protease and 3D polymerase.¹³³ Mutation rates have also been determined for HRV-A39 after experimental inoculation.³⁸ The calculated mutation rate after 5 days of replication *in vivo* was 3.4×10^{-4} mutations/nucleotides over the whole ORF, and specific hyper-variable mutation sites were located within VP1, VP2, VP3, 2C, and 3C sequences.³⁸

Clinical Features

Experimental inoculation studies have enabled detailed observations of the time course of clinical manifestations of HRV infection.^{21,42,49,54,56,104,165} Following inoculation with virus, the first signs of illness are usually sore or scratchy throat with an onset as soon as 16 hours postinoculation, followed by malaise and rhinitis. The first nasal symptoms are rhinorrhea, which usually begins with a watery discharge. During the peak of the cold, the discharge becomes mucoid or purulent, and is accompanied by nasal congestion, cough, and headache. Low grade fevers can occur in infected children, and are uncommon among adults with HRV infections. The latent period after infection is generally 1 to 2 days, and peak symptoms generally occur between 2 and 4 days following inoculation. Most colds are either over or are clearly subsiding within one week; cough and nasal symptoms that persist for two weeks or longer suggest either secondary bacterial sinusitis,²²¹ or else a second infection with a different virus.¹¹⁹ There are few symptoms to differentiate HRV illnesses from those caused from other viruses. Studies of adults indicate that HRV may be more likely to present with

sore throat, have prominent nasal symptoms in most individuals, and are less likely to be associated with fever.¹²

HRV can also cause infections of the middle ear, sinuses, and lower airways. Eustation tube dysfunction occurs in about half of experimentally induced or naturally occurring HRV infections.^{25,160,173} Studies of natural colds also link detection of HRVs in the nasal secretions or middle ear fluid to otitis media (OM).^{9,29,32,196,211,227,252} A prospective one-year study of the role of viral URI in OM enrolled 294 children between the ages of 6 months and 3 years, and the viruses most often detected were HRV and adenoviruses (27% of OM for each virus).³² Approximately one third of HRV infections were complicated by acute OM, and another 20% of cases had asymptomatic middle ear effusions. Another recent longitudinal study prospectively sampled nasal secretions of 1- to 5-year-old children and siblings at the onset of either cold or otologic symptoms.⁵ HRV infection was detected at least once in 70% of the children, and 44% of these infections were associated with either OM with effusion or acute OM.

To investigate effects of HRV on the paranasal sinuses, Gwaltney and colleagues⁸⁵ performed sinus computerized tomography (CT) scans during the peak symptom period following experimental HRV inoculation of 31 adults, and during the acute cold 27 subjects (87%) had swelling and or mucosal thickening and fluid collection in one or both of the maxillary sinuses (Fig. 18.13). A subset of the study subjects had repeat scans two weeks later, and these abnormalities had spontaneously subsided in 79%. Likewise, Puhakka et al.²⁰³ tracked findings on serial plain radiographs in individuals with naturally acquired common colds, and found that 38% developed mucosal thickening and either air fluid levels or opacification of the sinuses on day 7 of the cold. These abnormalities resolved without treatment on follow-up films obtained on day 21. Together, these findings provide evidence that HRV infections can cause acute sinusitis. Whether the illness is caused by HRV or a combination of HRV plus bacteria has not been resolved, but an important clinical point is that the illness subsided without antibiotic treatment.

In infants, HRV can cause bronchiolitis, which is a syndrome consisting of upper airway symptoms that progress to severe cough, wheezing, and tachypnea. In severe cases, significant air trapping and hypoventilation can lead to hypoxia

FIGURE 18.13. Computerized tomography (CT) scans during an experimentally induced human rhinovirus (HRV) infection. The initial scan obtained on day 4 postinoculation (**A**) shows bilateral effusions in the maxillary sinuses (arrows) and abnormalities in the right ethmoid sinuses (asterisk). The follow-up scan on day 13 of the illness (**B**) shows some residual abnormality of the right maxillary sinus (arrows). (From Gwaltney JM, Jr, Phillips CD, Miller RD, et al. Computed tomographic study of the common cold. *N Engl J Med* 1994;330:25–30, with permission © Massachusetts Medical Society.)

and need for hospitalization for supportive care. HRV is second only to respiratory syncytial virus as a cause for bronchiolitis in infants.^{26,115,121,122,149,169,218} In patients with chronic asthma, HRV infections often begin with typical cold symptoms and then progress to asthma exacerbations that include severe cough, wheezing, shortness of breath, and in severe cases, hypoxia. Similar exacerbations of chronic respiratory symptoms also occur in patients with cystic fibrosis or chronic obstructive pulmonary disease (COPD).^{35,222,249,258}

Diagnosis

Differential

HRV infections cause respiratory symptoms that are quite similar to those caused by other respiratory viruses. Compared to influenza, HRV is less likely to cause fever, myalgia, and headache. In general, signs and symptoms of rhinitis are prominent, but there are few true differentiating features. The spring and fall peaks in HRV epidemiology follow the same general pattern as hay fever in many geographic locations. Differentiation of common cold and allergy symptoms can be difficult, but there are some differences in symptom profiles. Compared to respiratory allergies, HRV infections are of shorter duration, are more likely to cause sore throat, and are less likely to cause nasal and ocular pruritus.

Laboratory

VIRUS ISOLATION AND IDENTIFICATION

Tissue culture is a relatively insensitive method for HRV detection. Fetal lung fibroblast cells (WI-38, MRC-5, and Wis.L cells) or HRV-sensitive lines of HeLa cells are commonly used for HRV detection. Notably, HRV-C viruses cannot be cultured in standard cell lines, which lack the receptor to bind C species viruses, but have been propagated in organ cultures of sinus epithelium.²³ Typing of HRV-A and HRV-B species isolates is possible using specific antisera.

HRV detection is greatly improved through the use of RT-PCR^{67,111,147} or other molecular techniques,^{51,133} which are available mainly through research laboratories. The 5' untranslated region contains several highly conserved regions that are usually targeted for primer design (Fig. 18.14). Because HRV-C's do not grow in standard tissue culture conditions, partial genomic sequencing has been used to classify these viruses

into "types".²¹⁶ The regions usually targeted for genotyping are the 5' UTR, VP2-4, or VP1. Sequences in the capsid coding region are more variable, which helps to distinguish genotypes but also complicates the design of broadly applicable primers. Higher rates of success (close to 100%) have been achieved by targeting the 5' UTR.¹⁴⁸ Classification based on partial sequences must be considered as tentative, since recombination among HRV can occur.¹⁸⁶

Nasopharyngeal lavage specimens or swabs are the best specimens for HRV detection, and yields are lower from throat swabs.^{165,224} A "nose-blow" technique has been used to obtain nasal secretions for clinical research protocols using PCR-based diagnostics with good recovery rates.^{95,184,197} Viral transport medium containing a protein source such as gelatin or albumin helps to stabilize the viral capsid for best results with tissue culture or molecular techniques. Nasal swabs obtained at home and mailed to the laboratory also provide specimens suitable for analysis by molecular techniques.¹⁹¹

Prevention and Control

The cure for the common cold remains enigmatic. Many approaches have been explored, including nutritional supplements, immune modulators, antiviral agents, and mediator antagonists to block specific common cold symptoms.²³² Vitamin C has long been touted for common cold treatment; however, a meta-analysis of common cold treatment studies found no significant effects on either prevention or treatment.⁵⁵ A Cochrane review of clinical studies found evidence that zinc lozenges reduce common cold duration, but have significant side effects including bad taste and nausea.²¹⁹ Topical zinc was marketed as a homeopathic treatment for colds, but was taken off the market due to association with anosmia.³ Large-scale trials of Echinacea have provided no evidence of efficacy.^{15,233} There is evidence that warm drinks, as recommended for generations, can provide symptomatic relief from malaise and nasal symptoms without troublesome side effects.²⁰⁹

Improved knowledge of HRV molecular virology has led to several attempts to develop antivirals. IFN- α has antiviral effects *in vitro* and shortens the duration and severity of colds, but topical application led to nasal irritation and bleeding.^{63,92,94} Anti-ICAM-1 and soluble ICAM-1 were developed to prevent binding of major group viruses to their receptor.^{27,159,183} Capsid

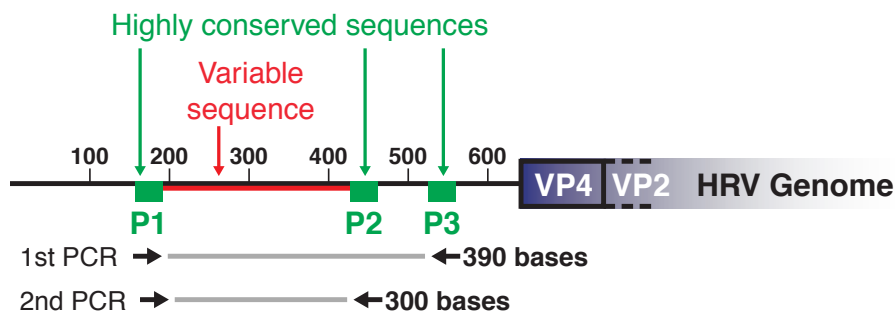

FIGURE 18.14. Selection of primers for polymerase chain reaction (PCR)-based diagnostic tests for human rhinovirus (HRV) infection. The most conserved sites in the HRV genome are in the 5' untranslated region in the area of stem loop structures that bind ribosomal proteins. These sites are targeted for primer design (P1, P2, P3) that can be used for single or nested reverse-transcriptase PCR. (Figure courtesy of Wai Ming Lee, PhD, University of Wisconsin-Madison.)

binding agents that bind to the VP1 pocket and inhibit viral binding and/or uncoating^{7,213,234} have shown modest antiviral effects and efficacy in clinical trials.^{93,95} An inhibitor to the 3C protease (rupintrivir) also showed broad anti-HRV activity *in vitro* and efficacy in clinical trials.⁹⁶ Unfortunately, these antiviral approaches have not so far led to development of a clinically useful medication. The molecules tested to date have been limited by combinations of modest efficacy, side effects, and/or drug interactions.²³²

Medications targeting specific symptoms can be helpful in relieving some aspects of the common cold. Examples include use of decongestants and topical ipratropium for relief of congestion and rhinorrhea, respectively.⁵⁹ Cough syrups are ineffective. Notably, marketing of combination cough and cold medications to children has been stopped by the U.S. Food and Drug Administration (FDA) due to reports of toxicity with overdoses, and even a small number of children receiving standard doses of these medications. A recent study suggests that vapor rub (petroleum jelly with aromatic oils) may relieve common cold symptoms, perhaps by stimulation of ion channels.¹⁸⁹

Perspective

The development of molecular diagnostic tests for HRV has led to a better appreciation of their role in respiratory illnesses, especially with respect to lower respiratory illness in young children and patients with chronic lung diseases. Findings from recent studies underscore the ubiquitous nature of HRV infections, and at the same time have led to some caution in interpretation of viral detection due to high rates of asymptomatic illness. That HRV is linked to a full spectrum of respiratory illness also raises questions about the nature of factors that modify illness severity. Identification of environmental and personal determinants of illness severity could provide new preventive strategies, and this is especially important for high risk populations.

Another revelation for common cold researchers was the discovery of the HRV-C species in 2006. After a hiatus of almost 20 years following the cataloguing of what most virologists considered to be the final HRV serotypes, clinical studies utilizing molecular diagnostics led to the discovery of another estimated 50 to 60 HRV types. There is growing evidence that HRV-C viruses may be more likely than other species to cause lower respiratory illness in infants and children, and acute exacerbations of asthma.

Finally, the cure for the common cold remains elusive. After some initial failures took the wind out of the sails of these efforts, the recognition that HRV infections are an important cause of lower respiratory illnesses has generated renewed interest in this effort. Recent advances in understanding the molecular pathogenesis of HRV illnesses, including HRV-C, provide reason for renewed optimism that this goal will be achieved.

HISTORY

Reports of icteric disease in ancient Chinese literature, as reviewed by Zuckerman,⁴¹⁹ and a letter from Pope Zacharias to Archbishop St. Boniface of Mainz during the 8th century AD describing an outbreak of jaundice may refer to hepatitis A; however, it cannot be distinguished from jaundice attributable to other causes. It was not until the 17th, 18th, and 19th centuries that scattered epidemics of jaundice affecting diverse populations were recorded more frequently. The disease, which was common in military troops, was called *campaign jaundice*. In time, an infectious cause was suspected by several clinicians, especially for the milder, more contagious forms called *epidemic catarrhal jaundice*.¹⁴³ In 1912, Cockayne⁵⁴ used the term *infectious hepatitis* to describe this epidemic form of the disease, and support for a viral cause gained favor from that point forward.²⁶⁰

Epidemiologic studies and human volunteer experiments performed during and after World War II confirmed the viral cause of hepatitis A and defined its relatively short incubation period and its fecal–oral mode of transmission. These studies also demonstrated the uniqueness of this disease from *homologous serum jaundice*, another form of hepatitis having a longer incubation period.^{30,153,154,205} In 1947, MacCallum²³⁵ introduced the terms *hepatitis A* and *hepatitis B* to categorize these diseases, terms that were adopted in 1973 by the World Health Organization (WHO) Expert Committee on Viral Hepatitis.⁴⁰¹ Between the mid-1950s and early 1970s, the studies of Murray²⁷⁰ and of Krugman et al^{205,207} at the Willowbrook State School for the mentally handicapped were instrumental in further defining the seroepidemiologic relationships between hepatitis A and B that eventually led to the evaluation of new methods for the immunoprophylaxis of these diseases. One of the hepatitis viruses, designated MS-1, was transmitted primarily by the fecal–oral route. The disease was highly infectious, had a relatively short incubation period of 4 ± 2 weeks, and defined classic viral hepatitis type A. The MS-1 strain of hepatitis A virus (HAV) was later used to infect adult volunteers,³⁰ leading to the identification of the virus in their feces by immune electron microscopy, as reported by Feinstone et al¹⁰¹ in 1973. Highly sensitive immunoassays were subsequently developed for the detection of HAV antigens and specific antibodies,¹⁶² culminating in the development of immunoglobulin M (IgM)-specific anti-HAV tests to distinguish recent HAV infection from a previous infection.²²³ In 1967, Deinhardt et al⁷⁹ provided the first evidence for propagation of HAV in small primates, leading to the subsequent recovery of the CR326 strain of human HAV from an experimentally infected *Saguinus mystax*.²⁵² In 1979, Provost and Hilleman³⁰⁴ were successful in cultivating and serially

passaging this HAV strain in cell culture—an important step that ultimately contributed to the development of a vaccine.

VIRUS CLASSIFICATION

HAV is a nonenveloped, positive-sense, single-stranded RNA virus classified within the family *Picornaviridae* that otherwise include many medically and veterinary important pathogens subclassified into 12 genera based on genotypic and serologic characterization (Fig. 19.1). HAV differs from other picornaviruses by several attributes, as reviewed by Martin and Lemon²⁴⁹: (a) HAV is resistant to high temperatures, low pH, and drugs that inactivate many picornaviruses; (b) HAV replicates very slowly and generally without cytopathic effect in cell culture; (c) nucleotide and amino acid sequences, as well as predicted sizes of several HAV proteins are dissimilar; and (d) only one serotype of HAV has been identified, and one antigenic neutralization site is immunodominant. Therefore, HAV has been classified as the type species of a separate genus—*Hepatovirus*—and is still the only identified member of this genus. One other distinct species of picornavirus found in chickens and other birds, avian encephalomyelitis virus,²⁵¹ was tentatively classified within the *Hepatovirus* genus on the

basis of a close phylogenetic relationship to HAV.³⁵¹ However, based on substantial molecular divergence in several proteins and its polyprotein translation mechanism, this virus has been assigned recently to a separate new genus within the *Picornaviridae* family—the *Tremovirus* genus.

VIRUS HOST RANGE AND EXPERIMENTAL MODEL SYSTEMS

HAV infects humans and nonhuman primates. Serologic and experimental infectivity studies in nonhuman primates using acute-phase sera from HAV-infected patients have revealed that HAV can be transmitted to chimpanzees (*Pan troglodytes*)^{78,82,256} and other Old World primates, such as vervet (*Chlorocebus* sp.), African green monkeys (*Cercopithecus aethiops*), rhesus and cynomolgus macaques (*Macaca mulatta* and *M. fascicularis*), as well as several species of New World primates, such as tamarins (*Saguinus* sp.), marmosets (*Callithrix* sp.), squirrel (*Saimiri* sp.), and owl monkeys (*Aotus* sp.).^{18,79,165,307} Disease in nonhuman primates resembles that in humans but is usually milder.³⁰⁷ There are several reports of isolation of HAV-related viruses from Old World monkeys in the wild, several of which have significant sequence variation and minor

FIGURE 19.1. Phylogenetic relationship of hepatitis A virus (HAV) and simian HAV (SHAV) to representative species of other *Picornaviridae* genera. The relationship was examined by mid-pointed rooted neighbor-joining tree based on P1 (capsid) amino acid similarities using Clustal alignments (accession numbers for sequences of selected picornavirus strains are indicated in parentheses). Bootstrap values (%) are illustrated at nodes, and the genetic distance per amino acid per site is shown by the horizontal bar. The grouping in 12 genera is marked by colored boxes. HAV appears most closely related to tremoviruses (avian encephalomyelitis virus, AEV).

antigenic differences with human HAV^{45,94,274,376} (see the Diversity of the Infectious Agent section). The simian virus isolated from an African green monkey caused severe hepatitis in African green monkeys, rhesus macaques, and tamarins but not in chimpanzees (although the virus replicated and the animals seroconverted).⁹⁴ Correspondingly, after 20 passages in marmosets, human HAV MS-1 was more virulent for marmosets but was attenuated for chimpanzees.⁴⁰ This suggests that host, species-specific variants may have been selected. To date, no rodent animal model has been shown to be susceptible to HAV, although experimental infection in guinea pigs resulted in virus replication in the absence of clinical disease.¹⁶⁶ Chimpanzees, tamarins, and marmosets have been most extensively used as animal models of HAV infection.

HAV is usually difficult to adapt and grow *in vitro*. The virus was first isolated *ex vivo* in marmoset liver explant cultures and was subsequently propagated in continuous fetal rhesus monkey kidney cells³⁰⁴ and in a variety of different types of mammalian cells. Primary African green monkey kidney (AGMK) cells, primary human fibroblast cells, and continuous human diploid lung (MRC5) cells often have been used because of their suitability as potential vaccine substrates. Cell lines derived from AGMK (e.g., BS-C-1, Vero), fetal rhesus kidney (FRhK4), or human hepatoma (PLC/PRF/5) tissue also have been useful for studying virus replication and for propagating large amounts of virus.^{71,106,308} Surprisingly, HAV also replicates in cells of guinea pig, porcine, or dolphin origin.⁸⁷

Wild-type HAV strains collected from infected patients usually replicate very slowly and to relatively low titers in cultured cells, often requiring weeks or even months and blind passages to reach maximal titers. With continued *in vitro* passage, however, the virus becomes progressively adapted to growth in cell culture, replicating more rapidly and achieving higher titers.^{57,59,71} During this process, the viral genome accumulates several mutations (see the Molecular Determinants of Hepatitis A Virus Adaptation to Cell Culture and Attenuation *In Vivo* section). Even when well adapted, HAV usually takes several days to weeks to reach maximal concentrations of propagated virus, achieving typical yields of 10^6 to 10^8 50% tissue culture infectious doses (TCID₅₀)/mL of virus. Recently, a subpopulation of human hepatoma cells (Huh7) has been selected that support efficient growth of wild-type HAV strains without requiring further genetic adaptation.²⁰² These cells may prove useful to characterize wild-type HAV strains isolated from patients and environmental samples.

In contrast to many other picornaviruses, HAV usually has few or no visible effects on the host cell. Thus, detection of HAV multiplication has usually required indirect methods: immunologic assays for viral antigens and hybridization or real-time polymerase chain reaction (RT-PCR) assays for HAV RNA. Radioimmunofocus or infrared fluorescent immunofocus assays can be used to quantify infectious HAV, select viral clones, and measure neutralizing anti-HAV antibodies.^{66,222}

As with other positive-strand viruses, purified genomic RNA, whether extracted from virions or produced synthetically from cloned complementary DNA (cDNA) of cell culture-adapted HAV, is replication competent when transfected into permissive cultured cells.⁵⁸ Accordingly, using synthetic RNA in cell culture and also applying findings from other picornaviruses, it has been possible to elucidate several features of the HAV replication strategy.

MORPHOLOGY AND PROPERTIES OF HEPATITIS A VIRIONS

Virion Structure and Physicochemical Properties

HAV is a nonenveloped, approximately 27-nm spherical virus particle as first determined by Feinstone et al.,¹⁰¹ who used immune-electron microscopy and negative staining techniques on stool specimens collected from acute-phase hepatitis A patients (Fig. 19.2). Mature HAV virions purified from feces collected from infected humans or chimpanzees band at 1.32 to 1.34 g/cm³ in cesium chloride (CsCl) and sediment at approximately 156S to 160S in neutral sucrose solutions.³⁴² Additional populations of viral particles with different sedimentation characteristics have been isolated from human feces and cell culture. Particles with lower density that band at about 1.27 g/cm³ in CsCl and sediment at 70S to 80S are abundant in feces collected during early infection and probably represent empty capsids devoid of genomic RNA (also called *procapsids*) (see Fig. 19.2). Other premature or defective particles, including particles harboring capsid protein precursors, also can be observed.^{26,224,342} These alternative structures are

FIGURE 19.2. Hepatitis A virus (HAV) particles observed by electron microscopy. A: Immune electron micrograph of HAV particles from human stool heavily coated with and aggregated by human convalescent antibody. **B:** Negative staining showing 27- to 28-nm HAV particles with cubical symmetry purified from human stool. Both virions (*closed arrowheads*) and procapsids devoid of genomic material (*open arrowheads*) can be found. (Courtesy of Dr. Stephen M. Feinstone, Food and Drug Administration, Bethesda, MD.)

FIGURE 19.3. Hepatitis A virus (HAV) genome organization. The positive-strand RNA genome contains a single open reading frame (ORF), 5' and 3' untranslated regions (UTRs), is linked at its 5' terminus to the virus-encoded protein 3B (also referred to as VPg), and is polyadenylated [AAA(n)] at its 3' terminus. The ORF encodes capsid proteins 1A-D (also referred to as VP1-4 in the order indicated below the genome scheme; 1A or VP4-VP2 precursor also is known as VP0), protein 2A that is involved in particle assembly as 1D-2A (VP1-2A) precursor, and proteins 2B-C and 3A-D involved in genome replication. *Dotted lines* delineate commonly termed P1, P2, and P3 coding segments in picornaviruses, whereas primary cleavage of HAV polyprotein generates P1-2A and 2BC-P3 polypeptides (which sequences are indicated by *double-headed arrows*). Numbering above the genome indicates nucleotide positions within the wild-type HM175 strain of HAV (GenBank accession number M14707).

morphologically indistinguishable from typical HAV and have the same major surface antigens.

The HAV capsid encloses the viral genome, which is a linear, single-stranded, 33S RNA molecule of positive polarity approximately 7.5 kilobases (kb) in length.^{59,65,342} The viral genome encodes a single polyprotein that is subsequently cleaved primarily by the unique virus-encoded protease 3C to generate four capsid proteins (VP1-VP4) at its N-terminus and the nonstructural proteins involved in genome replication at its C-terminus (Fig. 19.3).

The HAV capsid contains 60 copies of the three major capsid proteins VP1, VP2, and VP3.^{120,342} Attempts to determine the atomic structure of HAV by X-ray crystallography have not been successful, although such studies have provided high-resolution images of virus particles from several other picornaviral genera. Medium-resolution images of the HAV particle, obtained by cryo-electron microscopy (Fig. 19.4) and generated by R. H. Cheng and collaborators (personal communication, 2011), suggest that there are prominent features at the icosahedral surface of the particle around fivefold and threefold axes of symmetry but no marked depression around the fivefold axes in contrast to the canyon found in enteroviruses.²⁵⁰

Hepatitis A Virus Resistance to Physical and Chemical Agents

In common with the enteroviruses, HAV is stable at low pH.³²⁷ It retains most of its infectivity when subjected to pH 1.0 for 2 hours at room temperature and is still infectious after 5 hours. The thermal stability of HAV, however, is considerably greater than that of other picornaviruses.³⁴⁴ Incubation of the virus for at least 4 weeks at room temperature (25°C) results in only a 100-fold decrease in infectivity.^{259,350} Significant loss of infectivity starts to occur with exposure at 60°C for short periods, and infectivity is destroyed almost instantaneously by heating above 85°C at neutral pH.^{285,305,344}

HAV has been found to survive for days to months in experimentally contaminated fresh water, seawater, wastewater, soils, marine sediment, live oysters, and cream-filled cookies.³⁵⁰ Outbreaks of hepatitis A have been reported following ingestion of partially cooked bivalve mollusks, suggesting that even steaming may be insufficient to destroy the virus in this

food source. In addition, HAV infectivity is highly resistant to drying, and infectious virus has been recovered from acetone-fixed cell sheets. The virus is also highly resistant to detergents, surviving a 1% concentration of sodium dodecyl sulfate, as well as to organic solvents such as diethyl ether, chloroform, or trichlorotrifluoroethane.^{294,344} Thus, solvent-detergent inactivation procedures do not reduce the infectivity of HAV, explaining why hepatitis A transmission has occasionally been associated with the administration of high purity, solvent-

FIGURE 19.4. Medium-resolution image of the structure of the hepatitis A virus (HAV) particle as revealed by cryo-electron microscopy. The solid kite defines a protomer that is likely occupied by single copies of each capsid protein VP1, VP2, and VP3. Five copies of such a protomer are linked at the fivefold (5 \times) axis of symmetry to form a pentamer assembly subunit. The mature particle contains 12 pentamers arranged on an icosahedral surface or 60 copies of each individual capsid protein. Threefold (3 \times) and twofold (2 \times) axes also are indicated. Coloring is based on the distance from the center of the particle, with *yellow* depicting exposed regions at the surface of the particle. (Courtesy of Profs. R. Holland Cheng, University of California at Davis, Davis, CA, and Tatsuo Miyamura, National Institute of Infectious Diseases, Tokyo, Japan.)

detergent-treated clotting factor concentrates.²²⁷ These properties of the virus are likely to contribute significantly to its ability to spread through the environment and to cause common-source outbreaks of hepatitis.

Inactivation of HAV was reviewed by Coulepis et al.⁶³ Appropriate measures rely on autoclaving (121°C for 20 minutes), exposure to chlorine-containing compounds (sodium hypochlorite, 3–10 mg/L at 20°C for 5–15 minutes or free residual chlorine concentrations of 2.0–2.5 mg/L for 15 minutes),²⁹⁴ or to a quaternary ammonium formulation containing 23% hydrogen chloride (HCl). HAV also is inactivated by incubation in 3% formaldehyde for 5 minutes, or in 70% ethanol for 60 minutes, and by β -propiolactone or ultraviolet irradiation.²⁵⁸

GENOME STRUCTURE

Genomic Organization

Similar to all picornaviral genomes, the HAV genome is a single-stranded RNA molecule of positive polarity that can be divided into three parts (see Fig. 19.3): (a) a relatively lengthy 5′ untranslated region (UTR) that does not have a cap structure at its 5′ end but instead has a 2.5 kDa, covalently bound, virus-encoded protein—VPg (also known as 3B)³⁸⁹; (b) a single, large open reading frame (ORF) encoding a polyprotein of approximately 2,227 amino acids in length that is proteolytically processed into structural (P1-2A) and nonstructural (2B-C and P3 or 3A-D) viral polypeptides; and (c) a short 3′ UTR of 63 nucleotides that is followed by a poly(A) tail of varying lengths (40–80 nucleotides) typical of picornavirus genomes. Complete sequence lengths range from 7,470 to 7,487 nucleotides excluding the 3′ poly(A) tail.

The HAV genome is very rich in A+U bases (62%) as compared to the median A+U base composition of 54% found among other picornaviruses—a feature that is likely to affect base-pair composition and biologically relevant folds of the genome. As in other picornaviruses, however, the HAV genome also is predicted to exist as a circular entity with both 5′ and 3′ ends in close proximity to facilitate RNA translation to replication switches.²⁸⁴

Untranslated Regions

The nucleotide sequence of the HAV genome begins at the 5′ end with two uridyl residues typical of picornaviruses. The 5′ UTR is approximately 729 to 749 nucleotides long and has a high level of secondary RNA structure comprising several complex stem-loop structures (Fig. 19.5). RNA secondary structure and tertiary interactions (pseudoknots) within this segment of the genome have been established by a combination of (a) phylogenetic comparative sequence analyses to predict thermodynamically stable base pairing, (b) functional genetic studies, and (c) direct biophysical and nuclease mapping techniques with single- or double-strand-specific ribonucleases (RNases).^{41,215,336} Among HAV strains, the 5′ UTR appears to be the most conserved region of the genome ($\geq 89\%$ nucleotide identity among strains representing genotypes I, II, and III).⁴¹ All picornavirus genomes have secondary structural elements at their extreme 5′ end that differ in length and folding.²⁸⁴ In the case of HAV, the 5′ UTR has an unbranched terminal stem of very low free energy comprising the 41 5′ terminal nucleotides.

This element (stem-loop I; see Fig. 19.5) is likely to be important for RNA replication.

As in all picornaviruses, the most dominant structural unit in the HAV 5′ UTR is the internal ribosome entry site (IRES), which determines the initiation of viral translation in a 5′ cap-independent fashion (see Fig. 19.5). Depending on structural similarities at the secondary and tertiary levels, and the nature of cellular translation factors required to initiate translation, picornaviral IRESs are divided into four groups.²⁸⁴ The HAV IRES makes up a group on its own, designated type III IRES, which is distinct from all other known IRESs.^{20,284} The boundaries of the HAV IRES were mapped by using bicistronic messenger RNAs (mRNAs) comprised of a first reporter gene followed by various segments of the HAV 5′ UTR that controlled translation of a second, downstream reporter gene. Characterization of their translation activities in reticulocyte lysates or in cell culture revealed that the IRES is located between nucleotides 154 and 735.^{43,125}

Between the 5′ terminal stem-loop I and the IRES lies a sequence of approximately 110 nucleotides (nucleotides 42–154) that includes (a) two pseudoknots (IIa and IIb, nucleotides 42–94),³³⁶ the sequence of which is highly conserved among HAV strains, and (b) a partially ordered polypyrimidine tract and a single-stranded region (nucleotides 95–154),¹⁴⁹ which are susceptible to naturally occurring mutations, particularly deletions.⁴¹ This 5′ spacer domain corresponds to the most variable segment in length and sequence among all picornaviruses.²⁸⁴ These sequences may function as replication elements and/or contribute essential virus–host interactions.

The 3′ UTR of HAV RNA shows a high proportion of differences between HAV strains (up to 20%). It has been less extensively studied than the 5′ UTR but also has a high propensity to form higher-order structures. Hypothetical structural models of the HAV 3′ UTR have been proposed based on probing with specific RNases and computer-aided predictions, suggesting that a pseudoknot structure is favored⁸⁵ (e-Fig. 19.1).

Structural Proteins and Replication Proteins

Uniquely among *Picornaviridae* genera, the primary cleavage of the HAV polyprotein occurs between the P1-2A and 2B-C-P3 segments of the polyprotein under the direction of the only protease encoded by the virus—the 3C protein^{184,248} (see Fig. 19.3). The P1-2A segment comprises four structural polypeptides (in order): VP4 (1A), VP2 (1B), VP3 (1C), and VP1 (1D), named according to their homologs in the poliovirus capsid based on relative molecular masses, with VP1 being the largest. These proteins are approximately 23, 222, 246, and 274 amino acids in length, respectively (Table 19.1).^{59,138,247} VP1, however, has a heterogeneous carboxy terminus,¹³⁸ reflecting a unique maturation mechanism. Whereas VP2, VP3, and VP1 comprise the viral capsid, VP4 is substantially smaller than its homologs in other picornaviruses and has never been experimentally determined to be part of the HAV capsid. The 2A protein of HAV does not encode a primary cleavage function as found in the 2A proteins of most other picornaviruses, neither is it involved in genome replication.²⁵⁰ HAV 2A functions in capsid assembly as a fusion precursor with VP1⁶⁰ and remains attached to some otherwise fully formed virions.⁹ In-frame insertions within the HAV genome of exogenous protein coding sequences, flanked by 3C cleavage sites at the 2A/2B junction, has resulted in replication-competent virus, further

FIGURE 19.5. Proposed RNA structure of the 5' untranslated region (5' UTR) of hepatitis A virus (HAV; wild-type HM175 strain, accession number M14707). Nucleotides (in blue) are numbered according to their positions within the HAV genome. Subdomains comprised of stem-loop structures are numbered sequentially (Roman numerals). Putative tertiary pseudoknots are represented by *dotted lines* to indicate possible interactions between nucleotides. The 5' terminal stem-loop structure (I), pseudoknot elements (IIa-b), and polypyrimidine tract/single-stranded region (see text) are represented by *yellow*, *pink*, and *gray-shaded areas*, respectively. The internal ribosome entry site (IRES) is delineated by the *blue-shaded area* and comprises RNA structures IIIa to VI (nucleotides 154–735). The two in-frame AUG initiator codons of the viral polyprotein are boxed. (Modified from Martin A, Lemon S. The molecular biology of hepatitis A virus. In: Ou J-H, ed. *Hepatitis Viruses*. Norwell, MA: Kluwer Academic Publishers; 2002:23–50, with kind permission from Springer Science+Business Media B.V.)

confirming that 2A has no function *in cis* with the remainder of the nonstructural proteins.²¹

Nonstructural proteins derived from the 2BC-P3 segment of the polyprotein probably all contribute directly to the assembly of the membrane-bound viral replicase complex (see Table 19.1). Proteins 2B and 2C, and probably also the precursor 2BC, are involved in directing the rearrangements of cellular membranes required for replicase assembly.^{130,369} It has been suggested that 2B, containing hydrophobic sequences, anchors the replicase complexes to altered intracellular membranes.¹³⁰ 2C has NTPase activity¹²⁶ and contains an RNA helicase sequence motif.⁸⁴

Among the P3 nonstructural proteins, 3D is assumed to be the viral RNA-dependent RNA polymerase, although no direct data exist. 3C has been crystallized and is a chymotrypsin-like cysteine protease^{3,23,409} (Fig. 19.6). It appears to be the only virus-encoded protease of HAV, which is responsible for all co- or posttranslational cleavage events within the HAV polyprotein except for those at VP4/VP2 and VP1/2A junctions.^{151,242} In addition, HAV 3C protease and/or its precursors 3ABC and 3CD also appear to cleave cellular IRES-transacting factors and adaptor molecules acting in interferon signaling pathways (see the Infectious Viral Life Cycle and the Pathogenesis and

TABLE 19.1 Hepatitis A Virus Structural and Nonstructural Proteins

Viral Protein	Number of amino acids	Function	Properties
1A = VP4	21–23	Capsid protein?	Found as 1AB precursor in immature particles Presence not demonstrated in virions
1B = VP2	222	Capsid protein	Contributes to the major neutralization antigenic site Heterogeneous C-terminus Also found as 1D-2A precursor in immature particles Contributes to the major neutralization antigenic site Only characterized as P1-2A and 1D-2A precursors Also found as 2BC precursor
1C = VP3	246	Capsid protein	
1D = VP1	272–274	Capsid protein	
2A	71	Essential for capsid assembly	Also found as 2BC precursor
2B	251	Probable membrane anchoring for the virus replication complex	
2C	335	NTPase and helicase activities	3ABC precursor associates with mitochondrial membranes
3A	74	Probable membrane anchoring for 3B	Covalently linked to the 5' end of the genome
3B = VPg	23	Initiation of RNA replication?	Cleaves all protein junctions except for 1D/2A and 1A/1B 3ABC and 3CD precursors cleave adaptor proteins of the host interferon signaling pathways
3C	219	Chymotrypsin-like cysteine protease	
3D	489	RNA-dependent RNA polymerase	

Host Immune Responses sections). P3 also generates protein 3B (also referred to as VPg), which is attached to the 5' end of both positive- and negative-strand RNAs,³⁸⁹ and protein 3A, which comprises a hydrophobic 21 amino acid stretch that is believed to anchor the 3AB precursor of VPg (3B) to cellular membranes and to target the 3ABC precursor to mitochondrial membranes.⁴⁰⁴

DIVERSITY OF THE INFECTIOUS AGENT

Genetic Diversity

HAV identification and initial characterization were done with strain MS-1 isolated in 1964 from the blood and stools of a patient in New York.^{101,204} In the mid-1980s, the first comparative study of the nucleotide sequences of HAV performed by

RNase T1 oligonucleotide mapping of eight strains originating from diverse geographic sources revealed a variation in the order of magnitude reported for other picornaviruses.³⁹⁰ Several other laboratories reported nucleotide sequencing of full-length genomes from several HAV strains isolated directly from the stools of patients (e.g., HM175; Australia, 1976),^{59,71} or after a few passages in small primates or cell culture (e.g., LA; USA, 1976),²⁷⁵ MBB (North Africa, 1978),²⁸⁶ and GBM (Germany, 1976).¹³⁶ Wild-type strain HM175 has been adapted to yield the widest range of mutants in cell culture, including attenuated, persistently infecting, cytopathic and neutralization-resistant variants (see the Molecular Determinants of Hepatitis A Virus Adaptation to Cell Culture section). Attenuated mutants of HM175,¹⁹³ CR326 (Costa Rica, 1960),²³¹ H2 (China, 1982),²⁴⁴ and variants of strains GBM³⁸⁴ and MBB¹⁶⁷ are the best characterized candidates for live attenuated vaccines,

FIGURE 19.6. Ribbon representation of the crystal structure of hepatitis A virus (HAV) 3C protease (PDB accession 2HAL).⁴⁰⁹ **A:** Ribbon is colored by secondary structure with red, helix; yellow, sheet; green, loop. Side chains of the catalytic triad (D84, H44, C172) are shown as spheres across the top of the active site. The side chain of H191, the primary residue responsible for the glutamine specificity in P1, is also shown as spheres. **B:** A stick representation of the LFFE-FMK inhibitor, which mimics substrate residues P1-P4, is shown bound in the active site. Spheres and sticks are colored by atom type. (Courtesy of Dr. Bruce A. Malcolm, Johnson and Johnson Infectious Diseases and Vaccines, Beerse, Belgium.)

FIGURE 19.7. Phylogenetic tree based on hepatitis A virus (HAV) sequences (168 nucleotides) in the 2A region. Statistically significant bootstrap values (%) are given at the nodes, and genetic distance per nucleotide per site is shown by the horizontal bar. Genotypes are indicated by Roman numerals, whereas subgenotypes are indicated by A and B. The country of origin is indicated for best characterized strains of genotypes I, II, and III. The prototype MS-1 strain of HAV (not shown) belongs to subgenotype IA. The only known representatives of genotypes IV, V, and VI were collected from Old World monkeys. (Modified from Lu L, Ching KZ, de Paula VS, et al. Characterization of the complete genomic sequence of genotype II hepatitis A virus (CF53/Berne isolate). *J Gen Virol* 2004;85:2943–2952, with permission.)

as reviewed by Flehmig et al,¹⁰⁷ Hu et al,¹⁶⁸ and Provost et al¹³⁰³ (see the Hepatitis A Vaccines section).

The genetic diversity of HAV has further been investigated by determining the partial genomic nucleotide sequences of 152 HAV strains recovered from various human or simian sources and geographical areas²³⁴ (Fig. 19.7). Following virus purification by capture with an HAV monoclonal antibody, reverse transcription of viral RNA, and amplification by RT-PCR,¹⁸¹ genotypic analysis was based on the nucleotide sequence of a short genomic segment (168 nucleotides) that encompassed the relatively variable 2A coding sequence (originally thought to span the VP1/2A junction).

Additional phylogenetic studies were more recently carried out using a wider range of HAV isolates that were under-represented in the initial genotyping studies. This included HAV strains from South America, North and Central Africa, and India. In addition, full-length VP1 sequences (900 nucleotides) were chosen to establish nucleotide comparisons, con-

sidering that several residues of VP1 contribute to the major immunodominant site of HAV. Overall strain variation in the complete VP1 gene was found to be higher than 20% at the nucleotide level and around 10% at the amino acid level.⁶²

The current view is that HAV circulates worldwide as a total of six genotypes ($\leq 85\%$ identity) with three genotypes (I, II and III) subdivided into subtypes A and B (86%–92.5% identity within subtypes)²³⁴ (see Fig. 19.7). Genotypes I, II, and III comprise all human strains, among which subgenotype IA and genotype III are the most prevalent worldwide (e-Fig. 19.2). Each of the three simian HAV genotypes are defined by a single strain isolated from naturally infected Old World monkeys, cynomolgus macaques (genotypes IV and VI),^{274,318} and African green monkeys (genotype V).³⁷⁶ All simian HAV strains have a typical signature sequence at the VP3/VP1 junction that distinguishes them from human strains.^{42,318,376}

Clusters within genotypes predominate in certain geographic regions (see e-Fig. 19.2), such as a group of subgenotype

IA strains with more than 97% identity that represent nearly all of the viruses from the United States, suggesting endemic spread. Other regions, such as Europe and Japan, have a greater genetic mixture of viruses, suggesting regular introduction of strains by travelers returning from endemic regions. A higher degree of heterogeneity than reported previously has been found in strains isolated in South America.⁶⁷

To better define the HAV mode of evolution in populations, full-length VP1 sequences of a collection of genotype IA HAV strains isolated in France from 1984 to 2001 were analyzed. This revealed a mean rate of 9.76×10^{-4} nucleotide substitutions per site per year, and an estimation of a synonymous substitution rate around 5×10^{-3} substitutions per site per year. The latter is clearly lower than that observed for other representative members of the family *Picornaviridae* and may be related to the slower replication cycle of HAV, its particular tropism, or its transmission mode.²⁶⁵

Virion Antigenic Structure and Diversity

Comparisons of the nucleotide sequences of various human HAV strains from widely separated geographic regions have demonstrated high amino acid conservation in the sequences of the viral capsid proteins (>70%). Likewise, viruses belonging to distinct genotypes elicit antibodies with substantial cross-neutralizing activity, suggesting that there is only one HAV serotype among human strains.³⁵³ A primate HAV strain recovered from a captive New World monkey (owl monkey) was considered to be a human (genotype IIIA) rather than a simian strain following biological characterization and sequence analysis^{42,318} (see e-Fig. 19.2). Conversely, in strains of HAV isolated from naturally infected Old World monkeys (cynomolgus and African green monkeys), some monoclonal antibodies are capable of distinguishing unique epitopes, indicating some degree of antigenic singularity in simian strains.^{274,376} However, whereas African green monkey virus from genotype V caused no disease in chimpanzees, it elicited an anti-HAV response that protected the chimpanzees against disease after challenge with the virulent human-derived HM175 strain.⁹⁴ These observations suggest that even simian and human strains of HAV demonstrate substantial antigenic cross-reactivity.

Neutralization epitopes of HAV are conformational and generally are not displayed on isolated HAV proteins. Correspondingly, neutralizing murine monoclonal antibodies do not recognize denatured capsid proteins, and antisera raised against proteins expressed by recombinant DNA techniques show only weak reactivity with native capsids and have very limited virus neutralization activity.¹⁷⁰ Most murine monoclonal antibodies to HAV compete with each other and are able to substantially block the binding of polyclonal human antibodies to virus in solid-phase competition immunoassays.^{171,354} Similarly, human and chimpanzee neutralizing monoclonal anti-HAV antibodies recovered by phage display have been shown to compete with murine monoclonal antibodies.^{199,326} This suggests that there may be only a limited number of antigenic epitopes that are closely clustered on the surface of the virus.

Antigenic variants of HAV that resist neutralization by murine monoclonal antibodies have been selected in cell culture by continued passage of HM175 virus in the presence of these antibodies.³⁵⁴ Sequencing of the genomic regions encoding their capsid proteins revealed single amino acid changes in each mutant with a limited number of changes confined to

VP3 (two mutations) and VP1 (four mutations).^{296,297} Similarly, in strain HAS-15 (Arizona, 1979), a small number of mutations that confer resistance to neutralizing antibodies also were selected in VP3 and VP1.²⁷³ Competition studies with these mutants confirmed the existence of an immunodominant site composed of residues of VP1 (at positions 102, 171, and 176) and VP3 (at positions 70 and 74) that are likely to be closely positioned on the surface of the HAV particle and reside on exposed loops that connect β strands of the capsid proteins. This feature is likely to distinguish HAV from enteroviruses, for which equivalent residues do not lie in close vicinity at the surface of the capsid.¹⁶⁰ A crystallographic structure of the HAV capsid would shed light on the conformational nature of the immunodominant antigenic site. An apparently distinct site involving C-terminal residues of VP1 has been identified from HM175 neutralization escape mutants.²⁹⁷ In addition, two continuous epitopes near the N-terminus of VP1 (residues 11–25) and within VP3 (residues 110–121), which elicit weak neutralizing activity as peptides also may represent secondary neutralization sites.^{34,95} In the case of poliovirus, the VP1 N-terminus is internally located in the virion capsid but is exposed during virus attachment to cells.⁴⁴

The finding of limited amino acid changes among multiple neutralization escape mutants suggests that there are important constraints to the antigenic or structural variations of HAV. Recently, however, several HAV variants bearing substitutions or deletions at or around the immunodominant neutralization site or secondary neutralization sites were isolated in sporadic cases or during outbreaks of hepatitis A. These strains showed at least partial resistance to antiserum generated against HAV vaccine or to murine monoclonal anti-HAV antibodies, suggesting a potential for the emergence of HAV antigenic variants or new serotypes in the population.^{62,119,123,292,323}

INFECTIOUS VIRAL LIFE CYCLE

Attachment and Entry

HAV has been shown to bind to a wide range of cultured animal cells, including nonpermissive cells. Although nothing is known about viral determinants involved in HAV cell attachment, it has been observed that mature virions attach relatively rapidly and in a calcium-dependent way^{25,352,394,412} but undergo comparatively slow uncoating with release of viral RNA into the cytoplasm about 4 hours postinfection.²⁷

A candidate cellular receptor (HAVcr1), a mucin-like class 1 integral membrane glycoprotein of 451 amino acids³⁷⁰ (Fig. 19.8A), was first identified in HAV-susceptible AGMK cells using an expression cloning strategy and a monoclonal antibody that blocked binding of HAV to the cell surface.¹⁹¹ A molecule with 95% amino acid similarity was concomitantly identified in an HAV-susceptible hybrid marmoset-Vero cell line.¹⁴ A human homolog of HAVcr1 (with 79% identity) was later shown to interact with cell culture–adapted HAV.¹⁰⁰ The N-terminal cysteine-rich immunoglobulin-like region of the HAVcr1 ectodomain is sufficient for binding HAV, but both this region and the mucin-like region are required for viral particle conformational changes leading to HAV uncoating³⁴⁶ (Fig. 19.8A,B). A soluble form of HAVcr1 also is able to neutralize wild-type HAV,³⁴⁵ providing additional evidence for the role of this molecule as the HAV receptor *in vivo*. Recent

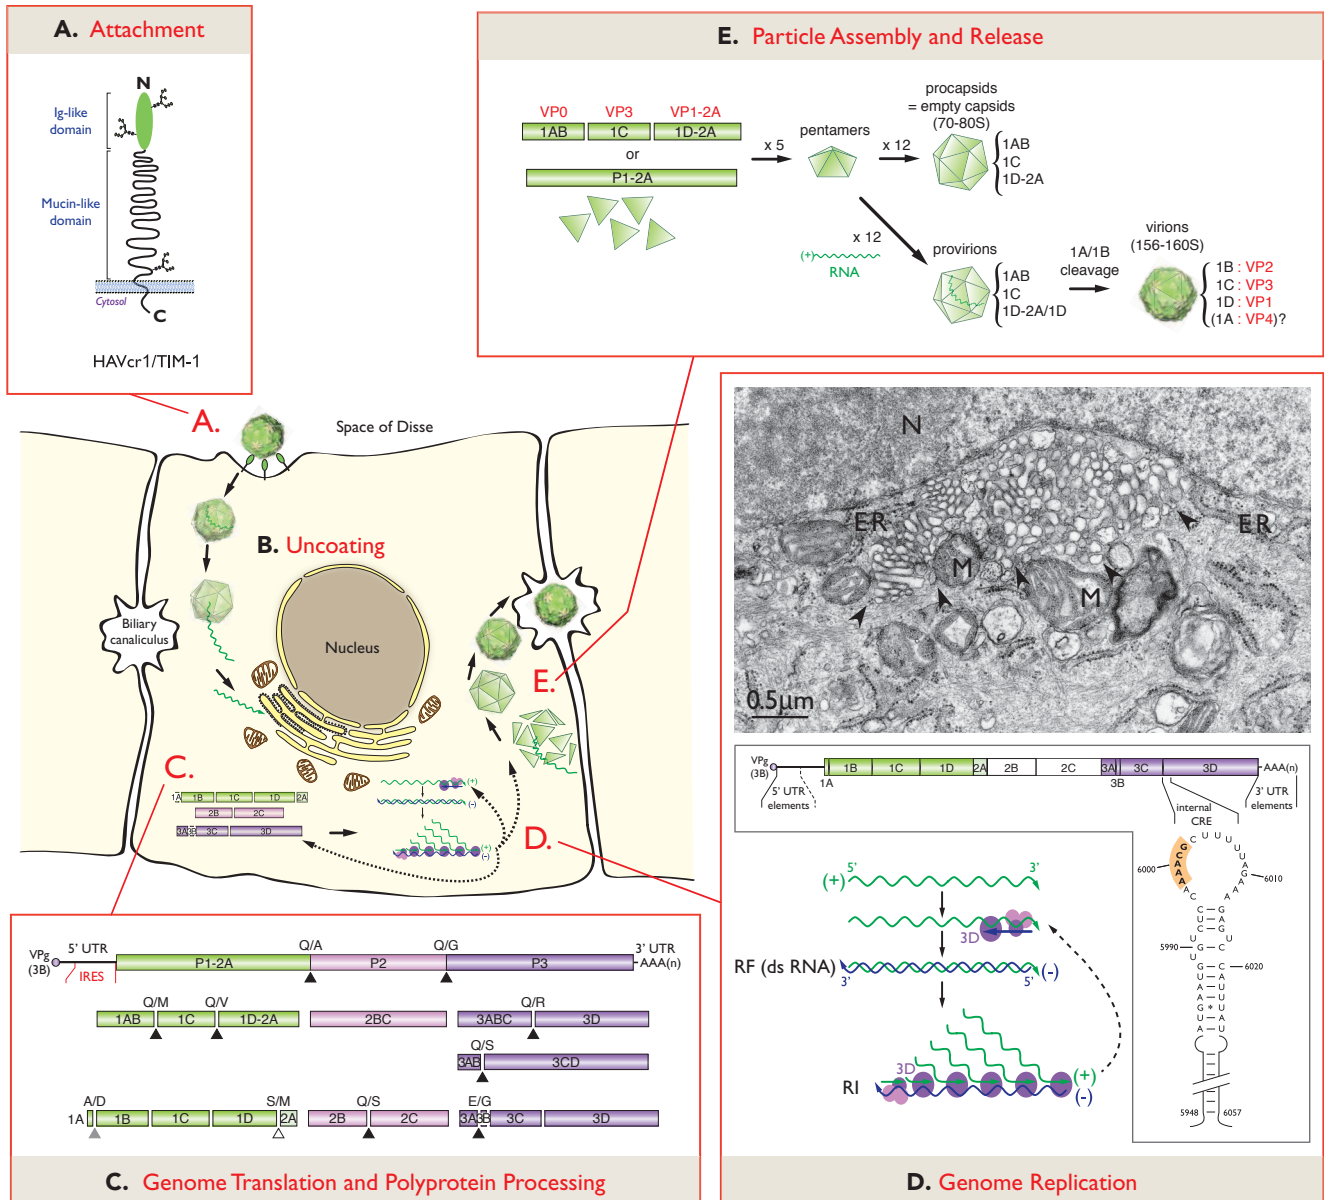

FIGURE 19.8. Hepatitis A virus (HAV) infectious life cycle. **A:** HAV enters hepatocytes by attachment to a cellular receptor, likely HAVcr1/TIM-1. This receptor, as schematically represented, comprises an N-terminal immunoglobulin-like domain and a mucin-like domain with three N-glycosylated sites (branched elements).³⁷⁰ **B:** Details of HAV uncoating remain largely unknown. **C:** Once released within the cell cytoplasm, virion RNA serves as a template for translation of the viral polyprotein, which is subsequently cleaved as depicted. Cleavages are carried out by HAV protease 3C at most junctions (black triangles), likely by a cellular protease at the 1D/2A junction (open triangle), or upon RNA encapsidation at the 1A/1B junction (gray triangle). Dipeptides representing cleavage sites between stable polypeptide precursors or mature proteins are indicated above corresponding boxes. **D:** Genome replication subsequently takes place within the virus-induced tubular vesicular network. The electron micrograph of FRhK-4 cells infected with cell culture-adapted HAV demonstrates rearrangement of cytosolic membranes into a network of tubular-vesicular structures (delineated by arrowheads), which appear closely associated with membranes of the endoplasmic reticulum (ER) and mitochondria (M) in the vicinity of the nucleus (N).¹³⁰ The positive-strand RNA is used as a template by the viral replicase complex comprised of polymerase 3D and other nonstructural proteins for minus-strand RNA synthesis, thereby generating replicating forms (RF). The minus-strand RNA serves in turn as a template for the synthesis of multiple positive-strand RNAs (replication intermediates, RI). *Cis*-active RNA elements (CRE) located at the 5' and 3' terminal regions of the genome, as well as within the 3D coding sequence are required for RNA replication. The stem-loop structure of the internal CRE, as depicted below the genome, includes a relatively lengthy stem (nucleotide numbering from HAV full-length genome) and a large loop that contains a motif boxed in orange, typical of all picornaviral CREs and necessary for their function.⁴⁰⁵ Newly synthesized positive-strand RNAs can be either engaged in translation, replication, or encapsidation, as represented by dashed arrows within the cell. (Electron micrograph courtesy of Dr. Rainer Gosert, Institute for Medical Microbiology, Basel, Switzerland.) **E:** Virion assembly is likely to proceed through indicated assembly intermediates, ultimately leading to the production of infectious virions, which are subsequently released into biliary canaliculi.

studies have identified *TIM-1*, an atopy susceptibility gene, as the gene that encodes HAVcr1.²⁶¹ The T-cell immunoglobulin mucin (TIM) gene family, particularly TIM-1, are cell surface receptors that are important in T-cell regulation and Th-cell differentiation (see the Clinical Features section). HAVcr1 is widely distributed in different tissues¹⁰⁰; thus, the tropism of HAV for the liver remains an enigma waiting to be resolved.

A surrogate entry mechanism of HAV has been proposed via immunocomplexes with HAV-specific immunoglobulin A (IgA), which are present in significant amounts during acute infection. This was based on the observation that HAV/IgA complexes can be endocytosed in hepatocyte cultures via the hepatocellular asialoglycoprotein receptor (ASGPR), which mediates uptake of IgA.⁸⁸ IgA-mediated transcytosis of HAV via polymeric immunoglobulin receptor also was observed *in vitro* and proposed as a mechanism for HAV to overcome the epithelial barrier of the intestinal tract.⁸⁶

Genome Translation, Polyprotein Processing, and Replication

The entire HAV life cycle occurs in the cytoplasm of the cell (Fig. 19.8). HAV genome translation and replication appear to take place in association with a tubular-vesicular membranous network specifically rearranged from cytosolic membranes by proteins 2B, 2C, or 2BC in HAV-infected cells,^{130,369} as is the case for other picornaviruses (Fig. 19.8D). The HAV 2B protein is localized predominantly in the endoplasmic reticulum (ER),⁷⁶ suggesting that the tubular vesicular structures may be derived from the ER.¹⁹⁷ Unlike enterovirus homologous proteins, HAV 2B has little, if any, effect on ER and Golgi calcium homeostasis, or on protein trafficking through the secretory pathway,⁷⁶ which is consistent with the hypothesis that hepatitis A virions may use the secretory pathway to exit the cell.²⁸

Translation

Uncoated RNA is translated via an IRES-dependent mechanism that involves cellular factors so that 40S ribosomal subunits bind and begin translation at the correct initiation codon and not at multiple AUG codons scattered throughout the 5' UTR. This mechanism contrasts with typical eukaryotic translation, in which 40S subunits recognize an m7G-cap at the 5' mRNA terminus (not present in the HAV genome) and then scan for the nearest AUG within an appropriate sequence motif.²⁰³ Initiation of HAV translation may start at either of two in-frame AUG codons at positions 735 through 737 and 741 through 743³⁶⁶ (see Fig. 19.5). Although either codon could function independently, selective deletion experiments have demonstrated that the second of these codons is preferentially used *in vitro* and in cells.³⁶⁶

The HAV IRES is far less efficient for directing translation in acellular systems and in various cell lines than are encephalomyocarditis virus (EMCV) and foot-and-mouth disease virus (FMDV) IRES, for example.^{32,43,125,396} Inefficient translation is likely owing to the fact that the HAV IRES uniquely requires intact cellular initiation factor eIF-4G to function, unlike other picornavirus IRESs that utilize a cleaved fragment of this factor,³¹ and that it probably competes poorly for this and other necessary cellular factors. HAV translation and replication are thus likely to depend on continued synthesis of host factors. Consistent with this hypothesis is the fact that HAV generally does not shut off host protein synthesis, unlike other picorna-

viruses. In the context of virus/cell competition, HAV appears to have adopted a naturally biased, deoptimized codon usage with respect to that of its cellular host.^{12,322} It has been hypothesized that this finely tuned strategy, observed specifically in the capsid coding region, might avoid competition between HAV and the host cell for cellular transfer RNAs (tRNAs), modulate translation kinetics, and allow proper protein folding to reach the highest viral fitness.¹²

HAV IRES activity appears to be modulated by several cellular proteins, including polypyrimidine tract-binding protein (PTB),^{51,129} glyceraldehyde 3-phosphate dehydrogenase (GAPDH),^{51,331,408} poly(rC) binding protein 2 (PCBP2),¹³³ and lupus autoantigen (La).⁶¹ GAPDH and PTB compete for binding to overlapping sites in the IRES (stem-loop III at the 5' end of the IRES)³³¹ (see Fig. 19.5). Although the mechanisms by which these cellular proteins modulate the translational activities of HAV IRES are unknown, it has been speculated that GAPDH may have a destabilization effect on RNA secondary structure, leading to translation suppression,⁴⁰⁸ whereas PTB may have a stabilizing action on higher-ordered RNA structures, thereby reversing GAPDH action and stimulating translation.^{129,408} In support of this hypothesis, a naturally occurring mutation that enhances translation in AGMK cells³³² decreases the affinity of GAPDH for stem-loop III in the IRES.⁴⁰⁸

Polyprotein Processing

Hepatoviruses follow a unique cleavage cascade distinct from all other picornavirus genera, as reviewed in Martin and Lemon.²⁴⁹ The primary, co-translational cleavage during HAV polyprotein translation is mediated by the unique virus-encoded protease (3C) at the 2A/2B junction, thus releasing a P1-2A precursor of 836 amino acids from the downstream nonstructural proteins^{128,248} (Fig. 19.8C). In most picornavirus genera, the primary polyprotein cleavage also occurs at the 2A/2B junction, although by a different mechanism; a unique sequence of amino acids (Asn-Pro-Gly-Pro) located at the 2A/2B junction possesses an inherent propensity to induce ribosome skipping, resulting in "cleavage" of the nascent polyprotein between Gly and Pro residues. Enteroviruses encode a second protease (2A) that autocatalytically cleaves its own N-terminus at the P1/2A junction.²⁸⁴

The key protease 3C carries out most other cleavages in the HAV polyprotein,^{151,182,242,330,368} as in other picornaviruses. The 3C-specific cleavage sites are formed by at least six residues surrounding the scissile bonds (amino acids at positions P4-P1 upstream, and P'1-P'2 downstream, of the cleavage site). HAV 3C is in general less discriminating than other picornaviral 3C proteases and recognizes Gln or Glu residues at position P1, any small residue or even charged residues with large side chains at position P'1 (e.g., Gln/Arg at the 3C/3D site), virtually any amino acid at position P'2, and residues with large side chains at position P4²⁴¹ (see Figs. 19.6 and 19.8C). The 3C-mediated cleavages occur according to preferential site order and also release stable intermediate precursors, such as 2BC, 3ABC, 3CD that appear to contribute specific functions in the HAV life cycle (see Table 19.1).^{210,301,310,404}

Cleavage at two junctions, VP1(1D)/2A and VP4(1A)/VP2(1B), is not carried out by the 3C protease. Uniquely among picornaviruses, VP1 is apparently released from 2A by cellular proteases.^{138,247} The C-terminus of VP1 is heterogeneous,¹³⁸ with a predominant form releasing a 2A protein of

71 amino acids. It has been proposed that, as for Mengovirus, cellular proteases may trim 2A sequences from VP1-2A to generate VP1 intermediate forms, as well as mature VP1 protein.^{138,247} The maturation cleavage at the VP4 (1A)/VP2 (1B) junction, similar to other picornaviruses, takes place in late stages of virion morphogenesis (see Fig. 19.8E) and occurs by an unknown, perhaps autocatalytic, mechanism to yield capsid proteins VP4 and VP2.

RNA Replication

Within the membrane-bound replicase complex, the virion RNA serves as a template for negative-strand RNA synthesis by the RNA-dependent, RNA polymerase 3D, generating double-stranded replicative forms (dsRNA) (Fig. 19.8D). This negative-strand intermediate then acts in turn as a template for the synthesis of multiple positive-strand RNA molecules, yielding replication intermediates (RIs). This asymmetric process suggests that mechanisms of replication of positive and negative strands may show some differences. Newly synthesized positive-strand RNAs can be translated into proteins, replicated, or packaged into new virions.

There are several genomic *cis*-active RNA elements (CREs) required for the initiation of viral RNA replication. Terminal sequences and/or structures present at the 5′ and 3′ ends of the genome, as well as the poly(A) 3′ terminal tail are likely to contain important replication elements. Consistent with this hypothesis, HAV genome-length RNAs that lacked the two 5′ terminal nucleotides (UU) or nucleotides 2 and 3 (UC), which are thought to be involved in a stem-loop structure (see Fig. 19.5), were not infectious.¹⁵⁰ One study suggested that elements required for RNA replication may extend downstream of nucleotide 151 of the 5′ UTR (i.e., beyond the polypyrimidine tract), because a genome containing only the 5′ terminal 151 nucleotides of the 5′ UTR followed by the EMCV IRES was noninfectious, in contrast to chimeric genomes containing the first 237 HAV nucleotides fused to EMCV IRES.¹⁸⁵ Likewise, whereas deletion of the pyrimidine-rich tract (nucleotides 96–139) did not alter viral replication in cell culture, deletions that also included nucleotides 140 through 144 immediately downstream of it (in a predicted single-stranded region (see Fig. 19.5) yielded a temperature-sensitive virus³³⁶ with defective RNA synthesis.³³⁸ The importance of the poly(A) 3′ terminal tail has been corroborated by observations that viral replication is delayed in cells transfected with genomes lacking part or all of the poly(A) sequence, and the poly(A) tail is concomitantly regenerated in progeny virus.²¹²

In addition, other internal CREs first identified in a rhinovirus genome²⁶² have been subsequently identified in several other picornavirus genera and are often located within genomic coding sequences. These elements comprise stem-loop structures of variable lengths with a common apical loop containing an “AAAC” motif.³⁵⁶ In poliovirus, the CRE was shown to template the uridylylation of 3B (VPg)—the small genome-linked protein—generating VPg-pUpU that functions as a protein primer for viral RNA synthesis.²⁸⁷ It is still debated whether both negative- and positive-strand RNA synthesis require CRE-dependent VPg uridylylation or whether negative-strand synthesis can be primed by VPg.³⁵⁶ For HAV, a CRE has been identified in the 3D coding sequence by combined phylogenetic and thermodynamic predictive strategies, as well as mutational analyses.⁴⁰⁵ HAV CRE comprises

a larger stem loop with lower free-folding energy than CREs of other picornaviruses (see Fig. 19.8D), suggesting that there are likely to be important differences in the details of the VPg uridylylation templated process for HAV. This is further supported by the apparent targeting of HAV 3A (and likely also the 3AB precursor of VPg) to mitochondrial rather than ER membranes.^{389,404} Evidence suggests that internal CREs function coordinately with the other *cis*-active RNA sequences and structures at the 5′ and 3′ termini of picornavirus RNAs to mediate RNA replication, presumably via ribonucleoprotein interactions that might be facilitated by the NTPase activity of 2C.³⁵⁶ Along these lines, interactions between HAV proteins 3C and 3AB with structures formed at both termini of the HAV genome have been documented *in vitro*.^{22,211,213,293}

Translation to Replication Switches

Interestingly, several cellular proteins may be involved in the finely tuned regulation of HAV RNA translation to replication switches, given that the same genomic molecule may be engaged in either process and that viral polysomes must be cleared of ribosomes before RNA replication can occur. Several sites for binding of GAPDH in the HAV 3′ UTR have been described.⁸⁵ Therefore, binding of GAPDH to both 5′^{51,331,408} (see earlier discussion) and 3′ termini of the HAV genome might promote the establishment of their close spatial proximity and have a role in RNA translation-replication switches. Viral protein and RNA syntheses also might be coordinated by the binding of full-length PCBP2 to the polypyrimidine tract of the 5′ UTR, whereas a truncated form of this cellular protein, which is cleaved by HAV 3C protease, has lesser affinity for HAV RNA, thus possibly facilitating the switch toward replication.⁴¹⁴ Similarly, another IRES *trans*-acting factor—PTB¹²⁹—is cleaved upon overexpression of HAV 3C protease, resulting in translation inhibition and hypothetically replication turn on.¹⁸⁹ However, the biological relevance of these observations is uncertain, because cleavage of these cellular factors has not been confirmed in HAV-infected cells, maybe as the result of low 3C quantities being present owing to protracted virus growth. HAV IRES was shown to be stimulated by polyadenylation in an acellular system, in contrast to FMDV IRES, suggesting a possible role for the 3′ terminal poly(A) residues of the genome in regulating HAV translation.²⁹⁰ More recently, poly(A)-binding protein (PABP) was shown to interact with polyadenylated HAV 3′ UTR.⁴¹³ This could hypothetically allow the bridging of HAV IRES via PABP-eIF4G interaction, resulting in the circularization of the RNA, such as in poliovirus and cellular mRNAs.¹⁵⁸ PABP also is targeted by HAV 3C protease in HAV-infected cells yielding a C-terminally truncated polypeptide that is able to bind to the polypyrimidine tract of HAV 5′ UTR. This might result in the curtailment of translation and the promotion of RNA replication.⁴¹³

Particle Assembly and Release

The mechanisms of HAV particle assembly are likely to differ significantly from those of other picornaviruses, consistent with detection of immature particle intermediates in HAV-infected cells.^{26,33} Recombinant vaccinia virus-mediated expression of HAV polyprotein or of capsid protein precursor P1-2A, on the one hand, and nonstructural protein precursor 2BC-P3, on the other hand, results in the assembly of

capsid-like structures.^{60,400} Using this system and C-terminally truncated P1-2A polypeptides, the presence of nonstructural protein 2A as a C-terminal extension of P1 was shown to be essential for both efficient 3C-mediated internal processing of P1-2A and the first step in virion morphogenesis.⁶⁰ The N-terminal domain of 2A is actually instrumental for assembling five copies of 1AB (VP4-VP2 or VP0), 1C (VP3), and 1D-2A (VP1-2A) polypeptides into pentamers, as a direct primary signal and/or as a consequence of its critical role in 3C-mediated processing of P1-2A, notably at the VP0/VP3 junction. However, whether pentamers are first assembled with five copies of uncleaved P1-2A precursors or cleaved VP0, VP3, VP1-2A polypeptides remains uncertain.^{33,60,300} (Fig. 19.8E). In other picornaviruses, the assembly of pentamers is initiated by N-terminally myristoylated VP4 protein.²⁸⁴ VP4 of HAV, however, is considerably smaller than VP4 proteins of other picornaviruses (at most 23 amino acids) and is not myristoylated, despite the presence of an internal consensus myristoylation signal.³⁶⁷ Twelve pentamers subsequently assemble into complete procapsids (empty capsids) or incorporate virion RNA to form provirions. N-terminal fusion of heterologous sequences to VP0 did not prevent the assembly of procapsids,⁴¹⁶ further suggesting that VP4 is not a critical determinant of HAV capsid assembly. The presence of the 3ABC precursor of 3C appears to improve P1-2A cleavage and particle assembly.²¹⁰ Cleavage at the VP1/2A junction begins after assembly of complete capsids and releases the mature VP1 capsid protein as well as larger VP1 polypeptides of intermediate lengths that, along with uncleaved VP1-2A, can still be detected in low amounts in procapsids and provirions.^{33,60,300} C-terminal residues of 2A are important for efficient cleavage at the VP1/2A junction,⁶⁰ which is likely carried out by a cellular protease that remains to be identified. Maturation cleavage of VP0 to release VP2 depends on RNA encapsidation, occurs by an as yet undetermined mechanism, and is associated with a conformational change to generate mature virions.²⁶ Cleavage of VP1-2A and VP0 into corresponding mature capsid proteins is accompanied by an increase in the specific infectivity of viral particles.^{26,60} The fate of 2A and VP4 in this process is unknown, and efforts to detect them in infected cells or virions have been unsuccessful.

Although a large proportion of the newly synthesized particles remains cell associated, there is extensive release of progeny virus into cell culture supernatant fluids by an as yet unknown mechanism. In polarized, human colonic epithelial cell cultures (Caco-2), release of virus occurs almost exclusively into apical supernatant fluids, mimicking the secretion of HAV across the apical canalicular membrane of the hepatocyte into the biliary system.²⁸ Interestingly, this process is largely blocked by an inhibitor of the cellular secretory pathway (Brefeldin A), suggesting that virus release may involve vectorial vesicular transport mechanisms.²⁸

MOLECULAR DETERMINANTS OF HEPATITIS A VIRUS ADAPTATION TO CELL CULTURE AND ATTENUATION *IN VIVO*

In contrast to the invariably transient nature of HAV infections in humans, infection of cultured cells, such as FRhK4,

BS-C-1, or MRC5, is typically not associated with any dramatic cellular injury and commonly leads to long-term persistence of the virus in cells. In addition, the HAV replication cycle in cell culture is typically slow. Most cell culture-adapted HAV variants attain maximal accumulation within 3 to 13 days but are not cytopathic. However, highly adapted variants of HAV that replicate rapidly (2–3 days) and cause cytopathic effects in cultured cells have been described.^{38,68,226,264} The development of a cytopathic effect depends on the interaction between particular HAV strains and cells at certain passage levels. In most cases, rapid cytopathic growth was selected by passaging HAV HM175 from persistently infected cells at intervals of 3 to 7 days.³⁸ Some strains of HAV, however, were cytopathic within several passages after direct isolation from human feces.²⁶⁴ Cellular injury appears to arise from the induction of apoptotic pathways leading to programmed cell death.^{38,130,131} Continuous passage of the virus in cell culture frequently results in a reduction in the ability of the virus to replicate in primates, resulting in attenuation of HAV virulence *in vivo*.³⁰²

Infectious cloned cDNAs of both wild-type and cell culture-adapted HAV strains are available and have made it possible to study the effects of mutations on the growth of HAV in cell culture and on its virulence for primates, as reviewed by Purcell and Emerson.³⁰⁸ The development of reporter subgenomic replicons lacking structural protein sequences that are capable of autonomous replication also have contributed to a better understanding of whether cell culture-adaptive mutations acted at the level of genome replication.⁴⁰⁷ Several concepts have emerged about mutations selected during adaptation or passage in cultured cells (Fig. 19.9): (a) mutations in gene 2B or 2C appear to be essential for the adaptation and efficient genome replication of HM175^{56,91,93,407} and probably other strains¹³⁵; (b) mutations in the 5' UTR (especially in the variable region around nucleotide 200) are not essential but enhance growth in a cell-type-restricted fashion^{75,115,116,117,137}—a cluster of mutations in the IRES appear to act by modulating translation efficiency in certain cells, perhaps through cell-type-specific interactions with accessory cellular proteins^{75,117,332}; and (c) other mutations or deletions throughout the genome, notably in 3A and 3D coding sequences, also contribute to enhanced growth of various HAV strains.^{135,136,201,264,308,415}

The effect of several cell culture-adapting mutations on HAV virulence has been evaluated following inoculation of tamarins (or occasionally chimpanzees) with virus or genomic RNA corresponding to wild-type HAV carrying cell culture-adapting mutations, or chimeras comprised of an attenuated HM175 variant and a virulent African green monkey strain. These experiments revealed that neither the 2B gene nor the 5' UTR (including the polypyrimidine tract and IRES) are implicated in HAV virulence,^{56,92,116,134,337} whereas the 2C gene (in particular, nucleotide 4563) plays a major role in virulence of HM175 in tamarins^{92,312} (see Fig. 19.9). The VP1-2A region also is an important determinant for HAV virulence, although not for adaptation to cultured cells.⁹² Genetic analysis of clinical viral isolates collected in patients experiencing self-limited acute, severe acute, or fulminant hepatitis failed to demonstrate clear associations of particular viral genome polymorphisms in the 5' UTR/IRES, 2B, or 2C sequences with disease phenotypes.^{111,113,237}

FIGURE 19.9. Substitutions existing between the cell culture–adapted HM175/p35 strain, used to produce inactivated hepatitis A virus (HAV) vaccines (GenBank accession number M16632), and its wild-type HM175 counterpart (GenBank accession number M14707) are represented by *dotted red lines* with their nucleotide position within the HAV full-length genome indicated below. Substitutions in the untranslated regions and those that result in amino acid changes are shown in *black font*, whereas silent changes are shown in *gray font*. Substitutions that are essential to cell culture adaptation and/or *in vivo* attenuation, or involved in cell-type modulation of HAV translation or replication (see text), are indicated by *curly braces*.

PATHOGENESIS AND HOST IMMUNE RESPONSES

Virus Replication *In Vivo*

Natural infection with HAV usually follows ingestion of virus from material contaminated with feces containing HAV. The sequence of events that begins with entry via the gastrointestinal tract and ultimately results in hepatitis has not been completely resolved. Consistent with the hypothesis that some cells of the gastrointestinal tract may be susceptible to HAV are studies in orally infected owl monkeys in which virus has been isolated from various levels of the gastrointestinal tract 3 to 35 days postinfection, and viral antigen has been identified by immunofluorescence in the epithelial cells of the intestinal

crypts and in cells of the lamina propria from the duodenum, jejunum, and ileum.¹³ Recognition that a transient rebound in fecal HAV RNA shedding has been observed in HAV-infected chimpanzees in the absence of a concomitant relapsing rise of virus-specific RNA in the serum or liver also suggests the possibility of an independent gastrointestinal replication compartment.²¹⁴ Whether this represents a *bona fide* site of replication of HAV remains to be clarified, however, because previous studies could not identify HAV antigen or genomic material in the intestinal mucosa of experimentally infected tamarins.^{204,253,254}

The primary site of replication for HAV is the liver, as demonstrated by virus detection in hepatocytes within days and even hours after infection.^{204,219,254,298} HAV is then released from

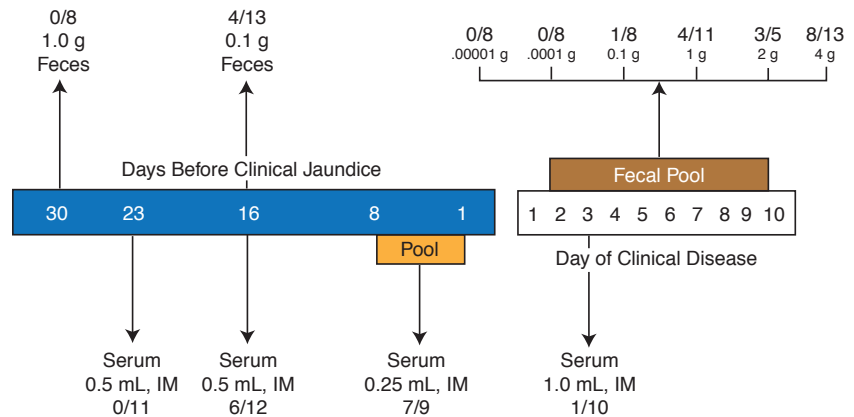

FIGURE 19.10. Clinically relevant immunologic and biologic events associated with hepatitis A virus (HAV) infection in humans divided into the four clinical stages. Following a period when virus in blood and feces has been shown to be transmissible, HAV RNA genomic material continues to be detected over a finite period of time (*dotted lines*) in some samples in the absence of documented infectivity (see text).

FIGURE 19.11. Relative levels of hepatitis A virus (HAV) infectivity observed for fecal and serum samples collected during the incubation period before clinical jaundice and the early stages of acute icteric hepatitis A. The number of subjects tested preceded by the number developing clinical hepatitis A is provided for each quantity of sample evaluated. In the absence of a diagnostic HAV assay in the 1960s to determine susceptibility, the number tested is not necessarily equivalent to the number of susceptible subjects; thus, the infectivity rate may be underestimated.²⁰⁵ IM, intramuscular.

infected hepatocytes into the bile canaliculi and passes into the intestine, after which it is detected in stools.^{308,328} According to this virus replication sequence, relatively high concentrations of HAV (up to 10^9 infectious virions per gram of stool)^{309,371} are shed in the feces before the alanine aminotransferase (ALT) level initially becomes elevated and before the onset of clinical symptoms or jaundice^{64,109,145,162,311} (Fig. 19.10). Communicability is highest during this interval.^{169,186,206,311} Early human studies have documented excretion of infectious HAV in stool specimens collected as early as 2 to 3 weeks before and up to 8 days after the onset of jaundice^{152,206} (Fig. 19.11). By contrast, transmission is severely curtailed during the acute and early convalescent stages of the disease, requiring increasingly larger quantities of fecal material to elicit an infection.^{206,207,233,386} In adults, viral particles are more often detected in the stools of jaundiced patients in contrast to patients who develop clinical symptoms without jaundice or who display no clinical disease.^{83,109} It is noteworthy that fecal shedding of presumably encapsidated HAV RNA can occur for several weeks after hepatitis develops, notably in infants,^{316,319,364} whereas recurrent shedding of HAV RNA has been observed in patients who have relapsing illness.³⁴⁷ In one study,³¹⁹ HAV RNA was detected in fecal samples from three preterm infants up to 4 to 5 months after they had developed acute hepatitis A. In addition to these observations, viral RNA and HAV antigen persist in the liver of infected chimpanzees more than 30 weeks after ALT levels have returned to normal and hepatic inflammation has resolved.²¹⁴

Virus is observed in blood (viremia) at about the same time extensive shedding of the virus in feces is occurring (see Fig. 19.10), although at levels generally 2 to 4 \log_{10} units lower than those in stool.^{35,55,219} Viremia precedes the appearance of clinical and laboratory evidence of hepatitis by at least 2 weeks, and its level tends to diminish dramatically during the period of liver enzyme elevation. In some situations, HAV appears to circulate in the blood enclosed in lipid-associated membrane fragments that may transiently protect the virus from neutralizing antibody.²²¹ In parallel with what has been observed in stool samples, HAV genomic material has been detected in the blood of infected patients and chimpanzees for much longer periods after onset of the disease than originally assumed (>10 weeks), although at concentrations several orders of magnitude lower than in acute-phase samples and always accompanied by

virus-specific antibody.^{35,112,219,280,410} The clinical significance of these observations has not been determined, because transmission or infectivity of blood components or fecal material containing HAV genomic material at these later time intervals has never been documented.

Evidence has been obtained for the replication of HAV in the oropharynx and salivary glands in orally inoculated chimpanzees and marmosets shortly after the appearance of virus in the blood; this could represent an early replicative event for the virus.^{55,298} Correspondingly, the presence of low titers of infectious virus in saliva collected from patients during the acute phase of the disease^{5,238,309} and in macaques infected by the intravenous route⁴ supports this conclusion. It is also possible, however, that the saliva may be contaminated by HAV entering the mouth during mastication through crevicular fluid that originates at the root–capillary interface, is released at the gingival surface, and contains serous material.¹⁶³ Finally, HAV antigen and/or genomic material has been observed in the kidney and spleen of infected owl monkeys, the biological relevance of which remains unknown.¹³

Immune Responses and Liver Disease

Early clinical studies in patients with acute hepatitis A reported either the absence of type I interferon³⁹⁵ or only transient increases in serum levels of interferons and type I interferon-induced human MxA protein^{180,228,411}—key components of the host innate immune responses that exert an antiviral effect on several viruses. Recently, a transcriptome analysis in HAV-infected chimpanzees revealed that the first evidence of an interferon response occurred at week 1 postinfection, as indicated by low-level increases of intrahepatic interferon-stimulated gene (ISG)-15 transcripts.²¹⁴ However, unlike many other genes, most ISG transcripts were up-regulated to a minimal degree and for only a few weeks in these HAV-infected animals. This paucity of type I interferon-induced ISG expression contrasts sharply with early and high-level induction of such genes in acute-resolving hepatitis C virus (HCV) infection. This is despite similar levels of viremia and 100-fold higher levels and much longer persistence of HAV RNA in the liver, and despite the presence of dsRNA in up to 10% of hepatocytes. The dsRNA corresponds to HAV replicative intermediates and forms (see Fig. 19.8D) and represents a potent pathogen-associated molecular pattern (PAMP) recognized by innate immune sensors.²¹⁴

FIGURE 19.12. Interferon-activating pathways disrupted by hepatitis A virus (HAV) 3C protease precursors. Cytosolic HAV RNA (double-stranded RNA [dsRNA]) is most likely sensed by the cellular RNA helicase MDA-5, which interacts through caspase-recruitment domains (CARD) with the adaptor protein MAVS localized on the mitochondrial outer membrane. This induces the activation of kinases (IKK α/β , TBK-1, IKK ϵ) of the I κ B complex and subsequent activation of latent cytoplasmic transcription factors IRF-3 and NF- κ B that results in the synthesis of interferon (IFN)- β as well as interferon-stimulated genes (ISG). Within an endosomal compartment, sensing of dsRNA by toll-like receptor 3 (TLR3) induces the dimerization of TLR3 and subsequent recruitment of the adaptor protein TRIF through shared toll/interleukin-1 receptor (TIR) domains. This also results in the signalization of IFN- β and ISG synthesis. Two different 3C protease processing intermediates derived from HAV P3 polypeptide block these signaling pathways by directing cleavage of the adaptor proteins: polypeptide 3ABC cleaves MAVS⁴⁰⁴ and polypeptide 3CD possesses altered substrate specificity compared to mature 3C that allows cleavage of TRIF.³¹⁰ (Modified from a scheme courtesy of Prof. Stanley M. Lemon, University of North Carolina, Chapel Hill, NC, USA)

Altogether, these observations suggest that HAV has evolved strategies to evade protective host innate immune responses induced by dsRNA that can be summarized as follows (Fig. 19.12). Initial studies revealed that HAV infection blocked interferon- β expression in cell culture by inhibiting interferon regulatory factor 3 (IRF3) activation mediated by retinoic acid-inducible gene I (RIG-I) or melanoma differentiation-associated gene 5 (MDA5); signal transduction appeared disrupted between RIG-I/MDA5 and downstream kinases.^{37,102} It was further shown that this disruption operated through cleavage of the adaptor molecule (MAVS) of the MDA-5/RIG-I-mediated signaling pathway by HAV 3ABC polypeptide. A stable and proteolytically active 3C protease precursor, 3ABC is directed to the mitochondrial membrane where MAVS localizes, owing to the presence of a mitochondrial targeting transmembrane domain in 3A.⁴⁰⁴ In addition, evidence indicates that the 3CD protease-polymerase precursor processing intermediate disrupts toll-like receptor 3 (TLR3) interferon signaling by directing the cleavage of

the corresponding adaptor molecule TRIF at two noncanonical 3C cleavage sites.³¹⁰ Thus, HAV proteins interfere with the two major cellular antiviral response pathways (RIG-I/MDA5/MAVS and TLR3/TRIF), possibly facilitating HAV replication during the clinically silent early weeks of infection.

The mechanisms responsible for hepatocellular injury and virus clearance in hepatitis A are incompletely characterized. The presence of large quantities of virus in the liver and stools prior to the onset of hepatic inflammation argues against a major direct cytopathic effect of HAV. Furthermore, in the absence of extensive adaptation of HAV to cell culture, HAV infections *in vitro* are noncytopathic and cell metabolism is relatively unaffected. Clinical hepatitis coincides with the appearance of robust humoral¹⁸³ and cellular (see below) immune responses. Because of this, the possibility of humoral immunopathogenesis has been examined, although no complement-dependent, antibody-mediated cytolytic activity has been demonstrated against HAV-infected cells.¹¹⁸ Circulating

immune complexes containing HAV and HAV-specific antibodies (primarily immunoglobulin M [IgM]) have been found during infection.^{17,39,246} However, although immune complexes may be present in the kidney,¹⁶⁴ immunoglobulin and complement deposits were not found at the sites of liver cell damage, and resolution of disease occurred at a time when antibody levels were rising and hepatitis A antigen could still be easily detected in the liver.²⁴⁵

Natural killer cells capable of lysing HAV-infected cultured cells have been isolated from patients with acute hepatitis A,¹⁶ suggesting that nonspecific immune mechanisms involving natural killer cells may play a role in hepatocellular damage. Clinical studies have revealed that lymphocytes recovered from the liver and blood of patients with acute hepatitis A contain human leukocyte antigen (HLA)-restricted, HAV-specific, CD8+ cytotoxic T cells that produce interferon- γ in response to HAV-infected cultured cells.^{108,209,239,379,380} This is consistent with the pathology of hepatitis A being largely the result of cell-mediated immune responses to the infection, as reviewed by Vallbracht and Fleischer³⁷⁸ and Siegl and Weitz.³⁴³ Highly conserved HAV-specific epitopes restricted by HLA-A2 and other alleles were recognized by CD8+ T cells collected from patients with acute, postacute, and resolved HAV infections.³²⁹ Most patients showed a multispecific T-cell response against at least two epitopes located within HAV VP1, VP2, VP3, 2B, 2C, and 3D regions of the HAV polyprotein, with the response directed against the 3D epitope being reproducibly immunodominant in HLA-A2 patients. These results and the existence of a single serotype suggest that immune escape in HAV infection does not appear to play a major role in the pathogenesis of this infection.

Although a dominant role for CD8+ T cells in both liver injury and control of HAV infections in humans has been postulated, a recent study in HAV-infected chimpanzees pointed to a potentially significant role for CD4+ T cells in HAV clear-

ance. CD4+ T cells produced multiple cytokines when viremia first declined, rebounded with a transient relapse of HAV fecal shedding, and remained detectable for many weeks until the HAV genome was cleared from the liver, whereas CD8+ T-cell frequency and effector functions did not appear to be as closely associated with virus control, at least in chimpanzees.⁴¹⁷ It is noteworthy that viremia declines rapidly following the appearance of the humoral response, suggesting that neutralizing antibodies also play a major role in clearing viremia.²²⁵ Correspondingly, a transcriptome analysis in HAV-infected chimpanzees revealed a remarkable activation of genes involved in B-cell development at 3 to 4 weeks postinfection.²¹⁴

EPIDEMIOLOGY

Hepatitis A is one of the most common causes of infectious jaundice in the world today and is frequently associated with recurrent epidemics. Humans and other primates are the only natural reservoirs for HAV. Based on incidence rates from confirmed acute HAV cases, the geographic distribution of HAV infection appears to be changing as countries improve their level of sanitation and personal hygiene (D. Shouval, personal communication, 2011)¹⁷⁸ (Fig. 19.13). In populations in which living conditions are crowded and sanitation is nonexistent or inadequate, prevalence studies reveal that infections occur at an early age and that close to 100% of children acquire immunity during the first decade of life^{110,141,179,257,361} (Fig. 19.14). In contrast, in modern urban societies or in developing nations where improvements in sanitation and personal hygiene have delayed infection, a reduction in anti-HAV prevalence among younger persons has been found.^{142,177,179,257,324,360} Thus, large segments of the population remain susceptible, and epidemics can occur after chance introduction of the virus to such an area. This has resulted in a paradoxical increase in the number

FIGURE 19.13. Estimated global hepatitis A virus incidence levels based on age-seroprevalence rates by country or region from samples that are representative of the general population, 2005. (Courtesy of Prof. Daniel Shouval, Hadassah-Hebrew University Hospital, Jerusalem, Israel.)

FIGURE 19.14. Age-specific hepatitis A virus seroprevalence curves in developed and developing countries and those in transition demonstrating age at which 50% of the people have immunity.¹⁷⁹

of cases observed in adults as they escape early childhood infection where disease manifestations are mild, and transition to adulthood where clinical disease is more overt and severe. An example of this changing epidemiology was the large epidemic that occurred in Shanghai in 1988 with more than 300,000 cases recorded.⁴⁰⁶

In the United States, the incidence of acute, symptomatic cases of HAV declined from 12.8 cases/100,000 population in 1980 to 0.9 cases/100,000 in 2008⁴⁹ (Fig. 19.15). At least a part of this decline is attributable to implementation of vaccine programs in high-risk populations (see the Prevention and Control section). The actual incidence of disease throughout the United States is estimated to be much higher because (a) many persons contract such a mild form of hepatitis that they do not seek treatment, and (b) physicians underreport hospitalized cases, although deaths are usually reported.

The incubation period for hepatitis A ranges from 10 to 50 days, with a mode of approximately 1 month, regardless of the route of infection.^{276,288,289} Higher doses of virus, however,

lead to a shorter incubation period.^{289,309} When two cases occur less than 14 days apart during a point source epidemic, they are more likely to be coprimary, rather than secondary, cases. Correspondingly, cases occurring more than 60 days apart presumably result from secondary spread of the infection.^{207,386} Although the median incubation periods for viral hepatitis A through E are distinctly different, there is considerable overlap; thus, knowledge of the incubation period is rarely useful in determining etiology. In addition, the patient may not know the time of exposure.

Of those with overt hepatitis A, from 21% to 53% are hospitalized, with the lowest being among children and the highest among persons 60 years of age or older. More than 70% of the adult clinical cases are jaundiced. In the United States, an estimated 100 persons die of fulminant hepatitis annually. Table 19.2 provides mortality data by age group for hospitalized patients with icteric hepatitis A increasing from 0.23% for those younger than 30 years to 1.8% to 2.1% for those older than 49 years. An overall case fatality rate of less than 0.015%

FIGURE 19.15. Incidence of acute hepatitis A per 100,000 population, United States, by year and Advisory Committee on Immunization Practices (ACIP) recommendations.⁴⁹ The inset covers the years 2000 to 2008 and shows the number of acute hepatitis A virus cases and the incidence/100,000 population in more detail.

TABLE 19.2 Predicted Outcome After an Infection With Hepatitis A Virus^a

Parameter	Predicted outcome	
	Children (<5 y) (%)	Adults (%)
Inapparent infection	80–95	10–25
Anicteric or icteric disease	5–20	75–90
Complete recovery	≥99	≥98
Chronic disease	None	
Mortality rate (hospitalized cases)		
<30 y	0.23	
30–49 y	0.3–0.6	
>49 y	1.8–2.1	

^aRefer to the text regarding atypical manifestations of hepatitis A.

was recorded among 310,746 cases of hepatitis A that occurred in Shanghai in 1988.⁴⁰⁶ This translated to a mortality rate of 0.3% to 0.6% for the 8,647 patients who were hospitalized, of whom 90.8% were between the ages of 20 and 40 years. Some of these patients had an underlying hepatitis B infection.

As expected, the presence of HAV in feces facilitates virus dissemination and accounts for the person-to-person mode of spread of hepatitis A. In the United States, the epidemiologic characteristics of acute hepatitis A cases reported to the Centers for Disease Control and Prevention (CDC) from 2001 to 2007 changed annually⁴⁷ to include household or sexual contacts with a person who had hepatitis A, international travel, men who had sex with other men, illicit drug users, and children and employees associated with daycare centers or with contacts of these individuals (e-Fig. 19.3). No risk factor was disclosed in more than 50% of the cases, although HAV-contaminated food was often suspected. Percentages are found to vary each year; however, a trend exists toward proportionally more cases being attributed to international travel, especially to Mexico and Central/South America, although sexual or household contact also is frequently implicated.

In contrast to this person-to-person mode of spread, sudden, explosive epidemics of hepatitis A within communities or confined populations usually result from fecal contamination from a single source,⁶³ such as drinking water,²⁶⁶ milk, or food.¹⁰⁴ Contamination of food can occur during cultivation, harvesting, processing, distribution, or preparation. Most food handlers with hepatitis A do not transmit HAV to patrons; when this occurs, however, the incriminated food is usually an item that is served uncooked or without further cooking (e.g., sandwiches, salads, pastries). Recent sources of large outbreaks have implicated frozen raspberries and strawberries, as well as iceberg lettuce.¹⁰⁴ An example of foodborne outbreaks in three states of the United States following the consumption of contaminated green onions³⁹³ is illustrated by an increase in the number of cases reported in 2003 (see e-Fig. 19.3). Several other foodborne outbreaks of hepatitis A have resulted from the consumption of raw or inadequately cooked oysters and clams obtained from water polluted with sewage.^{147,321,406} The role of mollusks has been that of virus concentrators of water polluted by sewage and not as a source for virus replication. During feeding, physiologically active bivalves (e.g., oysters or

mussels) can filter up to 10 gallons of water per hour over a short period during which HAV can be concentrated at least 100 times and persist for about 7 days.⁹⁶ As expected, non-bivalve shellfish (e.g., lobsters, shrimp) do not impart the same risk.

Hepatitis A molecular epidemiology is being widely and successfully used to characterize sources of infection and transmission patterns.²⁷² These molecular studies can provide strong epidemiologic links of disease transmission between persons who travel to an endemic area^{316,318,372} or during investigations of foodborne outbreaks.⁸ Such analyses are facilitated by the use of nucleic acid sequencing and phylogenetic evaluations to identify unique strains and determine genetic relatedness. Current phylogenetic analyses generally use a 315-bp nucleotide fragment from the 1D-2AB region of the genome because of its high degree of variability.²⁷² Population-based studies provide evidence that HAV is often transmitted by networks of persons who display similar risk factors for infection.³⁷²

As discussed previously, HAV communicability is apparently highest during the clinically silent incubation period when virus replication reaches a peak^{169,186,206,311} (see Fig. 19.11). By the time the patient seeks medical attention or the transaminases reach a peak and the patient becomes jaundiced, clinically relevant viremia also has significantly diminished. In one study, an acute-phase serum sample from a human with clinical disease was a million-fold less infectious when inoculated into chimpanzees than a stool sample collected on the same day,³⁰⁹ and serum samples from three other strains of HAV were at least 1,000 times less infectious. Despite these observations, HAV transmission through blood remains a rare but potential cause of posttransfusion hepatitis.^{19,148,164,219} In the past, the problem was amplified in neonatal intensive care units where infants developed a covert infection after receiving blood components from an infected donor. They subsequently transmitted the virus to healthcare workers and family members, presumably by the fecal–oral route.^{15,200,279,319} The rarity of transfusion-associated hepatitis A in adults probably can be attributed to several closely associated factors. First, the viremic stage is short, and the concentration of HAV in the blood is relatively low, as previously reviewed. The absence of an HAV carrier state²⁰⁷ also contributes to the rarity of HAV transmission through blood. Thus, for transmission to occur, an infected donor would have to donate blood to a susceptible recipient during a very restricted interval. In addition, because most recipients are given more than 1 unit of blood, an anti-HAV-positive unit may be transfused concurrently with the HAV-positive unit, thereby neutralizing the virus. Several of these scenarios often do not apply to neonates, which is why the risk is greater in this group. Current blood bank practices do not include specific screening of prospective donors for evidence of active HAV infection. However, nucleic acid testing for HAV is being done by the plasma industry, and whereas there is a wide variation in pool sizes and sensitivities, the general conclusion is that the HAV nucleic acid–reactive yield is relatively low with a range of 1 positive donation in 120,000 to 1,805,500 donations (S. Stramer, personal communication, 2011).

From 1989 to 1995, several outbreaks of hepatitis A occurred among hemophiliacs in Europe, South Africa, and the United States who received solvent- and detergent-treated factor VIII.^{243,315} Implicated lots were devoid of appreciable amounts of neutralizing anti-HAV and contained HAV

genomic material whose genetic sequence was identical to that obtained from infected patients. The solvent or detergent treatment had no effect on infectivity of this nonenveloped virus (see the Morphology and Properties of Hepatitis A Virions section) but could have been responsible for dispersing HAV in the product by releasing the virus from a nonneutralizable, lipid-associated environment. Effective heat-inactivation procedures, a preference for recombinant factor VIII, and vaccination have significantly reduced this risk.

Little evidence is found for transmission of HAV by exposure to urine or the nasopharyngeal secretions of infected patients.^{1,124,154,187,236,277} Other identified potential sources of exposure to HAV are nonhuman primates, usually chimpanzees, that have infected caretakers and other zoo personnel in close contact with them.^{74,81,159} In these situations, vaccination has been highly effective.

CLINICAL FEATURES

The outcome of hepatitis A can be extremely variable depending on the age when acquired (see Table 19.2). Patients with inapparent or subclinical hepatitis have neither symptoms nor jaundice. These asymptomatic cases previously went unrecognized but now can be identified by detecting biochemical or serologic alterations in the blood. Other patients can develop anicteric hepatitis or icteric hepatitis. Symptoms ranging from mild and transient to severe and prolonged can accompany anicteric or icteric hepatitis. Most patients recover completely; however, some develop fulminant hepatitis and die. As noted in Table 19.2, the disease is milder in children than in adults, complete recovery is the rule, and chronic disease has not been observed.²¹⁶ Hospitalization for and death caused by fulminant hepatic failure is age dependent. Whereas two-thirds of the clinical cases occur in children and young adults, more than 70% of the deaths are observed in patients older than 50 years. The mortality rate is considerably higher among patients with chronic hepatitis B or C who are superinfected with HAV,^{144,196,382,406} primarily when the underlying liver disease is advanced.

Symptoms and Signs

A typical course of acute hepatitis A can be divided into four clinical phases: (a) incubation or preclinical period (time between exposure and the first day of symptoms), (b) prodromal or preicteric stage, (c) icteric phase, and (d) convalescent period (see Fig. 19.10).

During the incubation phase, the patient remains asymptomatic despite active replication of the virus. A short prodromal or preicteric phase, varying from a few days to more than a week, precedes the onset of jaundice. In more than half of patients, the prodromal state typically is characterized by anorexia, fever, fatigue, malaise, myalgia, nausea, and vomiting. In hepatitis A, the transition from well-being to acutely ill occurs abruptly (within a period of 24 hours) in more than 60% of the cases, whereas the onset is more insidious in hepatitis B. Fever higher than 100.5°F is more common in acute hepatitis A than in acute hepatitis B.³⁸⁶ Diarrhea, nausea, and vomiting are more frequent in children than in adults.²²⁰ Weight loss of 2 to 10 pounds is common as a result of the anorexia that accompanies disorders of taste and smell.^{157,349} Older children

and adults often complain of right upper quadrant pain or discomfort as a consequence of hepatomegaly.³⁸⁶

The icteric phase of acute viral hepatitis is ushered in by the appearance of golden-brown urine caused by bilirubinuria, followed one to several days later by pale stools and yellowish discoloration of the mucous membranes, conjunctivae, sclerae, and skin. This icteric phase begins within 10 days of the initial symptoms in more than 85% of HAV cases,⁴²⁰ prompting patients to seek medical attention. Fever, if present, usually subsides after the first few days of jaundice.

Physical examination of the patient with a typical case of acute disease reveals the presence of jaundice accompanied by tenderness to palpation or percussion of the liver, which may be enlarged. Measurement by percussion is essential, because a reduction in size in a patient whose condition is deteriorating often heralds massive necrosis. Approximately 5% to 15% of patients have splenomegaly; however, generalized adenopathy is not a component of the disease and should trigger further investigation. Palmar erythema and spider angiomas may be observed.

Several atypical manifestations of hepatitis A have been reported, including the development of cholestasis, the possible induction of type 1 autoimmune hepatitis, extrahepatic manifestations, and relapsing hepatitis.^{188,325} HAV-infected patients who present with cholestatic hepatitis A initially have pruritus, fever, diarrhea, and weight loss. The serum bilirubin usually remains above 10 mg/dL for more than 12 weeks, whereas the ALT level is often less than 500 IU/L. Resolution of the disease is slow; however, recovery is complete within 2 to 8 months.^{127,334} HAV also has been associated with acute acalculous cholecystitis with jaundice on rare occasions^{268,283} and to trigger the onset of autoimmune hepatitis. Extrahepatic manifestations of hepatitis A are unusual,⁶⁹ although transient rashes are observed infrequently, as are arthralgia, arthritis, hemolysis, leukocytoclastic vasculitis, membranoproliferative glomerulonephritis, and pancreatitis.^{164,174,399} Finally, relapsing hepatitis occurs in 3% to 20% of the cases of acute hepatitis A. Recrudescence of the disease, usually less severe than the original episode, occurs 4 to 15 weeks after the initial symptoms have resolved. In some patients, only biochemical changes are observed. IgM anti-HAV either reappears or increases in titer, and HAV genomic material is detected in feces and serum. More than one relapse can occur, and enzyme elevations can persist for 5 to 12 months, although chronic sequelae are not observed.

Occasionally, more extensive necrosis of the liver occurs during acute viral hepatitis A, leading to severe impairment of hepatic synthetic processes, excretory functions, and detoxifying mechanisms. This entity, designated *fulminant hepatitis* if hepatic encephalopathy occurs during the first 6 to 8 weeks of illness or within 1 to 4 weeks after jaundice, is characterized by the sudden onset of high fever, marked abdominal pain, vomiting, and jaundice followed by the development of encephalopathy associated with deep coma and seizures.²⁸² A jaundice-to-encephalopathy time >7 days is an important prognostic indicator when determining the need for a liver transplant. This, however, is only one of several factors that are employed to determine survival in cases of fulminant hepatitis A. Other variables include coagulopathy (international normalized ratio [INR] >3.85), age (<10 or >40 years), elevated serum bilirubin and creatinine levels, intubation, and the use of

pressors.^{281,365} Although ascites, a bleeding diathesis, and decerebrate rigidity can lead to death in 70% to 90% of patients, in at least one study,³⁶⁵ the overall survival rate in fulminant hepatitis A among those spontaneously recovering and not requiring a liver transplant was 55%. Fortunately, fulminant liver failure is rare, occurring in less than 1.0% of the icteric patients hospitalized for acute viral hepatitis A.

Host factors that might influence the severity of hepatitis A infection are not well known. Viremia in patients with fulminant hepatitis A was found to be significantly lower than in classical forms of the disease, raising the hypothesis that fulminant hepatitis A might be associated with a strong immunological response.³¹⁴ A recent study found a relationship between HAV-induced severe liver disease and a six amino acid insertion in HAVcr1/TIM-1, a potential functional receptor for HAV^{52,198} (see the Infectious Viral Life Cycle section). This gene polymorphism appeared to offer protection against the development of atopic diseases while predisposing the individual to severe HAV-induced disease. A possible explanation for this may stem from observations that the long form of TIM-1 binds HAV more efficiently and that natural killer T cells expressing the long form of TIM-1 are more cytotoxic for HAV-infected hepatocytes.¹⁹⁸ In addition, it was found that the association of IgA with HAVcr1/TIM-1 enhances the interaction of HAVcr1/TIM-1 with HAV, suggesting a potential role for IgA/HAVcr1 interaction in the pathogenesis of HAV by enhancing viral entry in cells expressing low levels of HAVcr1/TIM-1.³⁶²

Laboratory Features

The initial laboratory evaluation of the patient with acute hepatitis should include a biochemical liver panel, complete blood count (CBC), and INR. Serum ALT and aspartate aminotransferase (AST) concentrations are highly sensitive indicators of hepatocellular injury. They provide a quantitative assessment of acute damage sustained by the liver, although the eventual outcome cannot be predicted from the level attained. Within hepatocytes, AST is found in mitochondria (80%) and the cytosol (20%), whereas ALT is limited to the cytosol, which may partially explain the aminotransferase patterns seen in acute hepatitis (i.e., ALT > AST). Damage to the plasma membrane leading to ionic and water shifts³⁷⁵ is followed by ballooning degeneration of hepatocytes (Fig. 19.16) and leakage of ALT from the cytosol. Consequently, high ALT:AST ratios (>1.4) are observed in uncomplicated acute viral hepatitis cases. Exceptions include those situations in which severe tissue necrosis develops, resulting in the release of mitochondrial AST into the blood. In these situations, the lactic dehydrogenase (LDH) enzyme also is significantly elevated. For the jaundiced patient, total serum bilirubin usually remains below 10 mg/dL, although levels of 20 mg/dL are occasionally observed. After reaching a peak in 1 to 2 weeks, the rate of decline is more gradual, with resolution occurring within 6 weeks of onset in most patients.³²⁰ As liver injury improves, discordant findings between serum and urine bilirubin can occur when elevated levels of serum bilirubin may not be accompanied by bilirubinuria owing to the *de novo* synthesis of a conjugated form of bilirubin (delta bilirubin) that is irreversibly (covalently) bound to albumin,³⁸⁸ thereby impairing its excretion in the urine.

Certain serum proteins (e.g., albumin, prothrombin, and fibrinogen) are synthesized exclusively or predominantly by the liver and can be affected by HAV injury. However, because

FIGURE 19.16. Classic acute viral hepatitis. Lobular disarray characterized by anisocytosis, anisonucleosis, ballooning, and Kupffer cell hypertrophy (H&E, $\times 190$). (From Ishak KG. Light microscopic morphology of viral hepatitis. *Am J Clin Pathol* 1976;65(Suppl 5):787–827, with permission.)

the intravascular half-lives of the various plasma-clotting factors are relatively short (hours to days), measurement of both the INR and partial thromboplastin time may more accurately reflect early and potentially serious derangements in liver function than does measurement of serum albumin, which has a half-life of 3 weeks.

Generally, the patient with typical acute viral hepatitis has a normal or slightly reduced number of neutrophils and a relative lymphocytosis.¹⁵⁵ When the white blood count is more than 12,000/mm³, a more serious form of the disease should be anticipated. Although mild to moderate reduction in red blood cell survival is frequent in acute viral hepatitis,¹⁹⁵ the hematocrit and hemoglobin remain within normal limits. Occasionally, however, hemolytic anemia occurs, often in association with glucose-6-phosphate dehydrogenase deficiency.^{132,173,240} Rarely does agranulocytosis, thrombocytopenia, red cell aplasia, or aplastic anemia accompany acute viral hepatitis.^{69,97,271}

Histologic Findings

In acute hepatitis A, both degenerative and regenerative parenchymal changes coexist with a diffusely distributed accumulation of mononuclear inflammatory cells.¹⁷⁶ Lobular disarray (see Fig. 19.16) is accompanied by swollen hepatocytes (ballooning degeneration) with indistinct plasma membranes, enlarged nuclei, and a featureless cytoplasm except for some cytoplasmic remnants condensed around the nuclei (e-Fig. 19.4). Acidophilic

degeneration (apoptosis) also occurs with cells becoming shriveled and angulated while displaying increased eosinophilia. Both types of degeneration result in the migration of affected cells or cellular debris into the spaces of Disse and eventually into the sinusoids, where they are surrounded by Kupffer cells and undergo phagocytosis and digestion. Activation of Kupffer cells in the sinusoids and macrophages in the portal tracts results in marked hypertrophy and hyperplasia of these cells. The portal tracts are enlarged as a result of edema accompanied by a moderate to heavy infiltration of lymphocytes, although neutrophils and eosinophils can be present. Plasma cells are uncommon. Inflammatory cells can spill over into the adjacent parenchyma, a process called *interface hepatitis*; however, less than 25% of the limiting plate is involved. During the recovery stage, regeneration is prominent, as manifested by anisonucleosis, the presence of numerous bi- and trinucleated cells, and mitosis. The inflammatory response diminishes, although Kupffer cell hypertrophy persists for a few weeks. The damaged hepatic tissue is usually restored within 8 to 12 weeks.

In 5% to 10% of patients, focal necrosis gives way to zones of necrosis that bridge portal tracts or join portal areas to terminal hepatic veins.^{36,103} When this process involves entire lobules or adjacent lobules, the terms *submassive* (involving the central and middle zones of lobules) or *massive* (involving

entire lobules) are applied. The latter is characterized further by the proliferation of cholangioles in the periportal areas infiltrated by neutrophils (Fig. 19.17). Confluent hepatic necrosis is potentially a progressive lesion that can lead to fulminant hepatitis and death, which appears to be inevitable when necrosis involves more than 65% to 80% of the total hepatocyte fraction.^{121,335} Conversely, complete regeneration of the liver is observed in survivors.^{53,194}

In rare cases of acute viral hepatitis A accompanied by jaundice, severe centrilobular cholestasis associated with disruption of bile canaliculi and periportal inflammation is observed that sometimes resembles chronic hepatitis, which never occurs in hepatitis A. This appears to be more common in hepatitis A than in hepatitis B or C but is less common than in acute hepatitis E.^{139,334} Plasma cells are often prominent in this condition.

Just as it is difficult to determine the cause of acute hepatitis without serologic data, the pathologic changes in acute-phase liver tissue obtained from humans with different forms of viral hepatitis are qualitatively similar.^{103,176} In general, liver tissue from patients with acute hepatitis A has less conspicuous parenchymal changes (including focal necrosis, Kupffer cell proliferation, acidophilic bodies, and ballooning degeneration) and less occurrence of steatosis than does tissue from patients with acute hepatitis C; however, necrosis and mononuclear cell inflammation of the periportal region are more evident than in biopsies from patients with acute hepatitis B.^{2,103,208} In addition, the limiting plate is more likely to be disrupted in hepatitis A.

FIGURE 19.17. Acute viral hepatitis with massive necrosis. All liver cells have “dropped out.” Note proliferating periportal cholangioles and infiltration of stroma and portal areas with inflammatory cells (H&E, $\times 73$). (From Ishak KG. Light microscopic morphology of viral hepatitis. *Am J Clin Pathol* 1976;65 (Suppl 5):787–827, with permission.)

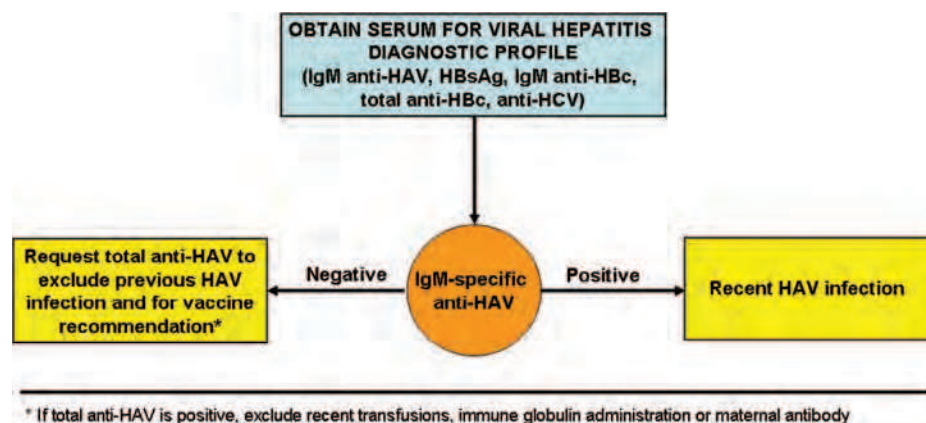

DIAGNOSIS

Because the agents of viral hepatitis often cannot be distinguished clinically and HAV superinfection of hepatitis B and C carriers can occur, serologic means are required for identification. The most favored acute viral hepatitis profile includes assays for IgM anti-HAV, hepatitis B surface antigen (HBsAg), IgM antibodies to the hepatitis B core antigen (IgM anti-HBc), and antibodies to HCV (anti-HCV). Idiosyncrasies of the assays, however, often make it desirable to perform ancillary tests that will confirm a positive response. Figure 19.18 is the approach used to diagnose acute hepatitis A, determine immunity, and assess the need for vaccination.

Amplification and sequencing of HAV RNA is being used to determine the genetic relatedness of isolates to identify infection sources and transmission patterns during epidemiologic case investigations^{80,172,315,316,318,372} (see the Epidemiology section). Immunocytochemical staining and physicochemical studies have been used to identify HAV and viral antigen in liver tissue from infected primates obtained early in the course of the disease.^{169,197,214,254,269,339} None of these methods, however, is practical in a clinical setting; they are not necessary unless incontrovertible proof for the presence of infectious virus or its source is needed.

To establish the diagnosis of acute or recent hepatitis A, blood samples are examined for the presence of acute-phase IgM-specific anti-HAV^{39,77,232} (see Figs. 19.10 and 19.18). Rarely, this test may be nonreactive when the patient first seeks medical assistance but will invariably become positive within the next 7 to 10 days.²³⁰ Conceptually, the *total* anti-HAV test also will be positive when the IgM anti-HAV assay is positive,

FIGURE 19.18. Serologic diagnosis of acute hepatitis A and immunity. IgM anti-HAV (immunoglobulin M antibodies to the hepatitis A virus); HBsAg (hepatitis B surface antigen); IgM anti-HBc (immunoglobulin M antibodies to the hepatitis B core antigen); total anti-HBc (immunoglobulin G [IgG] and IgM antibodies to the hepatitis B core antigen); anti-HCV (antibodies to the hepatitis C virus); total anti-HAV (IgG and IgM antibodies to the hepatitis A virus).

because it detects both immunoglobulin G (IgG) and IgM antibodies. Should it be negative, a false-positive IgM anti-HAV result should be entertained. The IgM anti-HAV antibody rapidly increases in titer over a period of 4 to 6 weeks and then declines to nondetectable levels within 3 to 6 months in most patients (range of <30 to >420 days), with persistence for more than 200 days in 13.5% of cases.¹⁹⁰ In more than 85% of patients, the liver enzymes will be normal before or at the time of disappearance of IgM anti-HAV. IgG anti-HAV eventually replaces the IgM antibody, persists for years after infection, and appears to confer lifelong immunity³⁴⁸ (see Fig. 19.10).

The total anti-HAV assay is used primarily to determine the immune status of an individual after vaccination or to assess risk in a person traveling to an endemic region or working in a high-risk area. In the absence of either IgM anti-HAV or an abnormal ALT level, clinicians can assume that the antibody being detected by this assay is of the IgG type, indicating previous infection with HAV—or successful vaccination—and protection against future infection. These conclusions are valid only if passively acquired antibody from blood components, maternal antibodies crossing the placenta, or immune globulin immunoprophylaxis can be excluded.

MANAGEMENT OF ACUTE VIRAL HEPATITIS

No specific treatment for acute viral hepatitis exists, and hospitalization is not ordinarily indicated. Therapy should be supportive and aimed at maintaining comfort and adequate nutritional balance. For most jaundiced patients, strict bed rest and prolonged confinement are probably not indicated.⁵⁰ In one study, for example, strenuous activity did not appear to have any adverse effect on the clinical course of acute viral hepatitis.³¹³

The diet should conform to the patient's appetite and wishes; it must, however, supply adequate protein and calories. As a general rule, modest consumption of alcohol (<30 g/day for men and <15 g/day for women) during convalescence (6–24 weeks after symptoms develop) does not seem to be harmful when the ALT level has decreased to less than 1.5 times the upper limit of normal.³⁷³ Nevertheless, because of the direct hepatotoxic effect of ethanol, abstinence from alcoholic beverages during the acute phase of hepatitis seems prudent. Finally, women who are taking oral contraceptives need not discontinue their use during the course of hepatitis.³³³

No indication exists for corticosteroids in the treatment of acute, uncomplicated hepatitis A. They have no effect on the rate of resolution of the underlying disease process and may increase the rate of relapse or result in death from fulminant hepatitis, especially if administered during the incubation or prodromal stage of infection.^{29,98,99} Conversely, a 4-week course of prednisone with tapering doses can hasten resolution in some patients who have developed prolonged, moderate to severe cholestasis, although complete recovery without therapy will eventually occur in all.³²⁵ Abruptly stopping prednisone or shortening the interval of therapy can result in a relapse.

Specific antiviral therapy is not yet available for HAV, partly because chronicity is not an issue and outcome of the disease is generally favorable. However, amantadine and interferon-alpha have been reported to interfere with HAV replication in cell culture.^{397,403} Amantadine was shown to inhibit HAV IRES-mediated translation in hepatoma cells. However, whether effective treatment doses could be transposed to the clinical setting remains to be demonstrated.

Treatment of fulminant hepatitis A is based on a thorough understanding of the pathophysiology of this disorder, which has been reviewed.^{299,359} Although mortality rates are relatively high, the immediate transfer of the patient to a liver transplant facility and the aggressive management of complications have been responsible for much of the improvement in survival rates. Orthotopic liver transplantation (OLT) or auxiliary partial OLT remain the only therapeutic modalities available for achieving a nonfatal outcome in the most severely affected patients with fulminant hepatitis A, leading to 1-year survival rates of 80% or more. The use of artificial or bioartificial liver support systems to perform all of the functions of the liver remains elusive and cannot currently be recommended outside of clinical trials.

PREVENTION AND CONTROL

Decisions concerning the prevention of hepatitis A must consider the immunobiology of the disease and the principal routes of transmission.¹⁶¹ The most effective control measures must prevent fecal contamination by infected individuals before their clinical disease becomes apparent. Thus, the most critical control measure is proper hand washing and the avoidance of work practices that facilitate contamination of hands when

taking care of children younger than 2 years, especially infected neonates where nosocomial transmission has occurred in relatives, family, staff, and physicians having direct contact with these individuals.^{15,90,200,279,319} Because the personal hygiene of young children is often difficult to control, they should be restrained from close contact with their susceptible playmates during the first 2 weeks of illness or for at least 2 weeks after the onset of jaundice.

Considering the low order of infectivity that is present during the icteric stage of disease in adults (see Fig. 19.11), many authorities have suggested that strict enteric precautions within the hospital are not necessary.^{255,267} In general, universal precautions should be adequate. Thus, isolation of patients in private rooms and the use of gowns or masks are unnecessary unless direct and excessive exposure to feces or fecally contaminated items is anticipated.

Immune Globulin Immunoprophylaxis

Prevention of clinical manifestations of hepatitis A through the administration of conventional intramuscular immune globulin (IGIM) was documented initially by Stokes and Neefe³⁵⁸ in 1944 during a common-source outbreak at a summer camp in which they observed an 87% reduction in the attack rate among those receiving IGIM. Similar immunoprophylaxis studies were carried out simultaneously in military personnel and institutionalized children.^{122,156} In each instance, IGIM was capable of preventing anicteric or icteric hepatitis A in 80% to 90% of the participants when given up to 6 days before the expected onset of illness, and doses as low as 0.01 to 0.02 mL/kg were found to be protective.

IGIM collected from any geographic region should be protective against HAV infection because only a single human HAV serotype exists. Current lots of IGIM are sterile preparations of concentrated antibodies that have tested negative for HBsAg, human immunodeficiency virus (HIV), and HCV. Although the U.S. Food and Drug Administration (FDA) has not yet set minimal concentration requirements for IGIM, the level of anti-HAV in the 16.5% formulation has ranged from about 33 IU/mL to 63 IU/mL in lots assayed between 2005 and 2007 (M-Y Yu, CBER, FDA, personal communication, 2011). Peak levels of antibody are achieved approximately 2 days after intramuscular administration, and the half-life of IgG is 23 days.

Studies performed in institutions and those conducted during community outbreaks indicate that IGIM can either completely suppress or modify the infection in HAV-susceptible persons, depending on the concentration of anti-HAV administered and the interval from exposure to treatment^{89,146,357} (e-Fig. 19.5). Larger doses of IGIM may provide protection lasting a few more weeks; however, more importantly, passive-active responses are curtailed, leaving a larger percentage of susceptibles available for infection following another exposure. IGIM is unlikely to be effective if given more than 3 weeks after exposure. The theoretical concern—that individuals might acquire HAV from persons who develop subclinical hepatitis after IGIM treatment—has not been borne out by epidemiologic investigations.³⁵⁷ Once the occupants of a household have received adequate prophylactic treatment, rigid isolation or compulsive cleanliness is not necessary. Commercial enzyme-linked immunosorbent (EIA) assays for anti-HAV following IGIM administration are usually unable to detect anti-HAV in the blood unless the procedure is optimized.⁷ When sera

were evaluated with a sensitive neutralization assay, however, low-level neutralizing antibody was found to persist for at least 14 weeks, depending on dose and concentration of antibody.^{114,353} Based on these observations, it can be assumed that very low levels of anti-HAV are sufficient to prevent infection.

Although IGIM may not interfere with the immune response to inactivated vaccines or to oral poliovirus or yellow fever vaccine,¹⁹² it may interfere with the response to other live attenuated vaccines such as measles, mumps, rubella, and varicella. Therefore, IGIM should be delayed at least 2 weeks after such immunizations, or, if IGIM is administered initially for hepatitis A prophylaxis, at least 3 months should pass before these other vaccines are administered.⁴⁸

Hepatitis A Vaccines

As nations improve their level of sanitation and hygiene, the age at which individuals will become infected is being delayed until adulthood, at which time the likelihood of developing symptomatic or serious illness is considerably higher (see Fig. 19.14 and Table 19.2). With the development, evaluation, and subsequent licensure of cell culture–derived hepatitis A vaccines in Europe in 1991 and the United States in 1995,^{11,218} the potential for long-term immunity has become a reality.

Two types of hepatitis A vaccines have been developed: either alum- or influenza virosome-adjuvanted, formaldehyde-inactivated vaccines that are available worldwide (Havrix, Vaqta, Avaxim, and Epaxal) (e-Table 19.1), or freeze-dried, live attenuated vaccines that have been used primarily in China and recently introduced into India.³⁴⁰ In general, these vaccines were initially evaluated in nonhuman primates, then their safety and efficacy were confirmed in clinical trials in humans. Both types use cell culture–derived HAV grown in human diploid cell cultures. In addition to these monovalent vaccines, the HAV-specific antigen has been combined with other vaccines such as the hepatitis B vaccine (Twinrix, Twinrix Junior, and Ambirix from GlaxoSmithKline [GSK]) or typhoid vaccines (ViATIM or Vivaxim from Sanofi Pasteur and Hepatyrrix from GSK). None of the HAV vaccines induce antigenic competition with other vaccines or increase the frequency of adverse events.^{6,24} Except for Epaxal, all other inactivated vaccines are free of thimerosal as a preservative.

All inactivated vaccines have similar immunogenicity and require two injections given 6 to 12 months apart, although this interval can be extended to 36 months. The vaccines should be administered by the intramuscular route, because suboptimal responses can result if the vaccine is administered in the gluteal region, especially in obese adults. Accelerated stability tests at 37°C for up to 3 weeks and after 15 months at 2°C to 8°C have revealed no loss of immunogenicity. In contrast, freezing may be deleterious to the product.

To prepare the alum-adsorbed Havrix hepatitis A vaccine, SmithKline Beecham (now GSK) extracted the cell culture–adapted HM175 strain of HAV from MRC5 cells¹⁴⁰ by freezing and thawing. This crude harvest is tested for the absence of extraneous agents, microbiologic sterility, and antigen identity²⁹¹ and then treated with formalin to ensure viral inactivation. Residual MRC5 cellular protein and traces of formalin and neomycin remain in the vaccine. No serious adverse events caused by this inactivated vaccine have been recorded in either outbreak settings or in field trials involving approximately 24,000 individuals.^{10,278} Postmarketing experience of unsolicited

events from a population of uncertain size precludes establishing reliable estimates of frequency of adverse events or their causal relationship to the vaccine.

The formalin-inactivated, alum-adsorbed, hepatitis A vaccine Vaqta, distributed by Merck & Co. Inc. is prepared from MRC5 cell monolayers infected with the attenuated strain of HAV CR326F.^{229,303} Antigen is extracted by lysis of infected cells and then concentrated, purified, and treated with formalin. The purified preparation is free from detectable MRC5 protein and contains only trace amounts of nonviral protein, DNA, bovine albumin, formaldehyde, and neomycin. The antigen is composed of monodispersed, full and empty, HAV particles. As with Havrix, undesirable side effects (e.g., injection-site pain/tenderness, fever, and headache) were mild in nature and of short duration. In a postmarketing surveillance study, no adverse events were identified among more than 42,000 individuals.²⁷⁸

Immunogenicity in adults, adolescents, and children 1 year of age or older is excellent, with protective levels of antibody (≥ 20 mIU/mL) being achieved in virtually all subjects after the primary injection. Two large efficacy trials involving more than 19,000 children have been conducted with the Havrix and Vaqta vaccines.^{175,391} The only cases that were observed in the Vaqta group occurred during the first 16 days, presumably among persons who had been infected before or shortly after the initial injection. The two cases that occurred in the Havrix group were relatively mild when compared with the cases in the control group.¹⁷⁵ Adverse events in these trials were mild and self-limited, and vaccine efficacy ranged from 95% to 100% (Fig. 19.19). During a 9-year follow-up period

FIGURE 19.19. Cumulative rates of symptomatic infection with hepatitis A virus in healthy children receiving hepatitis B surface antigen vaccine (control group) and hepatitis A vaccine (Havrix, GlaxoSmithKline, Research Triangle Park, NC). Timing of vaccine administrations is represented (arrows) with doses being given at 0, 1, and 12 months. Dashed lines indicate when surveillance was started, when postbooster surveillance was begun, and when the controlled trial was terminated at crossover. (Modified from Innis BL, Snitbhan R, Kunasol P, et al. Protection against hepatitis A by an inactivated vaccine. *JAMA* 1994;271:1328–1334, with permission.)

in a community-wide Vaqta study, no vaccine recipient developed hepatitis A despite continuing community exposure.³⁹²

Estimates using kinetic models suggest that protective levels of neutralizing antibody could persist in most vaccinees for 20 years or more.^{381,398} Development of IgM anti-HAV after vaccination is rare,³⁴¹ and the ALT level remains normal, so confusion with recent viral hepatitis should not be an issue. Immunogenicity data for infants are limited; however, initial studies have indicated excellent responses in seronegative infants. In contrast, responses in infants with pre-existing maternal antibody have resulted in a suboptimal response, especially in those under 6 months of age.^{72,105,295,374,377} A subsequent booster dose of vaccine, however, results in an anamnestic response in most, indicating that priming of the immune response had occurred despite the lower anti-HAV concentrations observed initially.^{72,105} Currently, the vaccine is only recommended for children 1 year of age and older. Other factors associated with reduced immunogenicity include immunosuppression from disease or drugs and advanced age.

The bivalent Twinrix vaccine contains a pooled formulation of the inactivated HAV and a purified recombinant HBsAg hepatitis B vaccine. It is indicated for susceptible individuals 18 years of age and older who are, or will be, at risk for exposure to both viruses. This risk includes (a) travelers to endemic areas of high or intermediate endemicity for both HAV and hepatitis B virus (HBV) who are at increased risk because of behavioral or occupational factors; (b) patients with chronic liver disease; (c) persons at risk through their work, such as emergency medical assistance teams; (d) men who have sex with men; (e) military recruits; (f) illicit drug users, injecting or noninjecting; and (g) persons with clotting factor disorders. In patients with chronic liver disease, baseline serology suggests that fewer than 40% may qualify for the bivalent vaccine because of natural immunity to one or the other virus. Primary immunization with the Twinrix vaccine includes three doses given on a 0-, 1-, and 6-month schedule, although a four-dose regimen (0, 7, and 21–30 days with a booster at 12 months) may be used if time is of the essence. Seroconversion and protective levels of anti-HAV were observed after one dose in 93.8% of healthy adult volunteers, although the anti-HBs response was unexceptional until after the third dose, as it is with the conventional hepatitis B vaccine. In contrast, responsiveness is reduced for both vaccines, but especially HBV, in patients with chronic liver disease with bridging fibrosis or cirrhosis. For the HBsAg nonresponders, booster injections with high concentrations of HBsAg (e.g., the Merck dialysis formulation) are sometimes required to achieve immunity. Adverse reactions have been rare and include hypersensitivity reactions and anaphylaxis.

At least two live attenuated hepatitis A vaccines used in China over the past decade have been reported to be safe and immunogenic and to achieve comparable seroprotection levels for more than 10 years following a single-dose immunization schedule.^{244,402,418} These vaccines contain the H2 and LA-1 strains of HAV that were adapted for growth in human diploid cell cultures at lower temperature (32°C). In a recent clinical trial comparing these two vaccines, a 95% protective efficacy to prevent clinical infection was observed in more than 450,000 children.⁴⁰² Herd immunity in the nonvaccinated population also was observed. Although subclinical infection may not be averted in all recipients, there is no evidence to indicate that the vaccine virus is shed in the feces or that it

FIGURE 19.20. Anti-hepatitis A virus (HAV) geometric mean concentration (GMC; mIU/mL) observed in persons after passive and active immunization and after natural HAV infection. (Modified from Lemon S. Hepatitis A virus: current concepts of the molecular virology, immunobiology and approaches to vaccine development. *Rev Med Virol* 1992;73–87, with permission.)

causes vaccine-associated infections. Accordingly, reversion to a more virulent strain has not occurred. Oral inoculation has been unsuccessful, however, even when higher doses of vaccine were administered.

Strategies for the Use of Hepatitis A Virus Vaccine and Immune Globulin

Anti-HAV Responses After Passive and Active Immunization

Qualitative differences in protective antibody responses are observed following active and passive immunization probably because of differences in the affinity of antibodies.²²⁵ Figure 19.20 compares anti-HAV responses in the following situations²¹⁷: (a) at 3 to 5 days after receiving 5 mL of IGIM (passive immunization), (b) at 6 to 12 months after one injection of live attenuated HAV vaccine, (c) at 6 to 12 months after two injections of inactivated hepatitis A vaccine, and (d) at 10 to 20 years after a natural infection. Despite these disparities, protection against disease is comparable, implying that very low and even nondetectable levels of anti-HAV may confer protection.

Pre-Exposure Prophylaxis

Although universal childhood immunization for hepatitis A is a worthy goal, it is unlikely that such a recommendation will be issued by policy makers in developing countries or regions with transitional economies, given the economic and political realities of global immunization programs. Even in developed countries, the integration of hepatitis A vaccination into routine childhood immunization schedules has been slow to materialize. Within the United States, however, several recommendations were formulated by the Advisory Committee on Immunization Practices (ACIP) beginning shortly after the vaccine was introduced in 1995, even though the annual number of prevaccination deaths from hepatitis A placed it at the bottom of the list of other infectious diseases for which vaccination was subsequently recommended. At first the focus was on vaccinating high- and intermediate-risk groups and children living in communities with the highest disease rates. In 1999, this was expanded to include children residing in states, counties, or communities that had consistently elevated rates of hepatitis A (≥ 10 cases/100,000 population or twice the national average).⁴⁸ The final step in this strategy came in

2006, when routine hepatitis A vaccination of children was recommended nationwide. Administration of IGIM was relegated to more specific indications (see later discussion).

A recent assessment of the impact of this novel immunization strategy revealed that the incidence of hepatitis A in 2003, when compared with a prevaccination baseline period (1990–1997), declined 76% to 2.6 cases/100,000 population³⁸⁷ (see Fig. 19.15). Although this decline was seen throughout the United States regardless of vaccination policy, it was more pronounced in those states where vaccination was implemented (88% vs. 53% decline in rate). A decline in the incidence rates also was seen in all age groups. A similar reduction in disease incidence in the vaccinated and older nonvaccinated population also was observed following universal immunization of toddlers 18 to 24 months of age in Israel, suggesting marked herd protection and the possibility that catch-up vaccination programs may not be necessary⁷³ (e-Fig. 19.6).

As shown in Table 19.3, immunization should be offered to persons traveling from industrialized countries to regions of the world where HAV is endemic and where the risk of acquiring hepatitis A is enhanced because of living conditions and the length of stay (e.g., Asia [except Japan]; Africa, Latin America and the Caribbean, eastern Europe, the Middle East, and the Commonwealth of Independent States). Routine immunization for U.S. military personnel could be reserved for those who regularly travel to endemic areas or those in rapid-deployment

TABLE 19.3 Risk Groups Potentially Targeted for Pre-Exposure Prophylaxis

- Travelers to or workers in foreign countries (including the military) where the risk of acquiring hepatitis A is enhanced
- American Indians/Alaskan natives
- Persons who work with HAV or with nonhuman primates
- Persons with chronic liver disease
- Men who have sex with men
- Persons who have clotting factor disorders
- Persons residing in areas where extended community outbreaks exist
- Refugees residing in temporary camps after catastrophes

units. For other soldiers, typical reassignment or deployment times of several weeks would be sufficient for generating a protective response to vaccination.

It has been reported that the incidence of symptomatic hepatitis A for a 1-month trip to a developing country is 3 to 6 cases/1,000 susceptible travelers.³⁵⁵ In contrast, the incidence rate is sixfold higher (20 cases/1,000) in persons whose travel arrangements or personal hygiene place them in jeopardy of acquiring an infection. In making a recommendation for vaccination, it is important to recognize that hepatitis A is contracted at least 100 times more frequently than is typhoid fever or cholera.³⁵⁵ For most travelers, vaccine alone will suffice if the first dose is administered at least 2 weeks prior to expected exposure to HAV. For both immediate and long-term protection of older adults (>40 years), immunocompromised persons and persons with chronic liver disease or other chronic medical conditions where the immune response may be muted, and who are planning to depart for an endemic area in 2 weeks or less, the simultaneous administration of inactivated hepatitis A vaccine with IGIM (0.02–0.06 mL/kg) should provide optimal protection with the stipulation that separate syringes and injection sites are used.^{46,385} The anti-HAV titers, however, are about twofold lower when compared with those observed when vaccine alone is administered but more than 100 times higher than levels considered to be protective.

At-risk individuals who are allergic to components in the vaccine or who do not elect to receive the vaccine can be given small doses of IGIM (0.02–0.04 mL/kg or 2.0 mL for adults) if the anticipated period of exposure is 2 to 3 months. Larger doses (0.05–0.06 mL/kg or 5.0 mL for adults) should be administered every 4 to 6 months for more prolonged exposure.

Vaccine also should be offered to staff and residents of institutions for the mentally disabled or to members of other relatively closed communities who are at high risk for acquiring hepatitis A. It also should be offered to preschool children attending daycare centers, including the staff, parents and siblings, and to any other group whose occupation, lifestyle, or behavior places them in the high-risk category (e.g., illicit drug users, injecting or noninjecting, and men who have sex with other men). Other groups that have been targeted for possible immunization for hepatitis A are listed in Table 19.3.

One of the more contentious recommendations concerns the administration of hepatitis A vaccine to patients with chronic liver disease, especially those with hepatitis B or C. Several reports have suggested that the occurrence of hepatitis A in these patients is associated with a higher frequency of severe illness or fulminant hepatic failure, leading to substantially higher case fatality rates.^{196,382} Other investigators, however, have reported conflicting data on the clinical course and outcome of hepatitis A in chronic liver disease.^{263,363} In the interim, it seems prudent to offer vaccination to all patients with chronic liver disease as recommended by the ACIP. Physicians should recognize, however, that no data indicate that a concurrent hepatitis A infection will place patients with chronic liver disease at increased risk for a life-threatening outcome unless they have advanced liver disease (e.g., cirrhosis).

Postexposure Prophylaxis

There has been considerable movement to revamp the strategy on postexposure prophylaxis favoring the use of hepatitis A vac-

TABLE 19.4 Advisory Committee on Immunization Practices Recommendations for Postexposure Prophylaxis Using Vaccine or Immunoglobulin M Alone

- Close personal contact (household and sexual contacts)^a
- Outbreak in childcare centers (staff and attendees; consider household members of diapered attendees)
- Common-source exposure (food handlers of index worker and patrons if identified and treated within 2 weeks of exposure)
- Outbreak confirmed in schools, hospitals, and work settings

^aConsider vaccine alone or both vaccine and immunoglobulin M if the contact shared illicit drugs with case.

cine over IGIM following exposure to HAV. Advantages include long-term protection, ease of administration, higher acceptability and availability, and comparable cost. Initial data was limited to experiments in marmosets and chimpanzees.^{70,306,317} Primates were vaccinated 1 to 3 days after being challenged orally or parenterally and were protected against hepatitis A disease or had an attenuated infection without virus shedding. A randomized, double-blind, active-control, noninferiority trial conducted in Kazakhstan and supported by the CDC, was designed to compare the efficacy of hepatitis A vaccine (n = 568) to IGIM (n = 522) in preventing laboratory-confirmed, symptomatic HAV infection when given to at-risk subjects within 14 days after exposure.³⁸³ This study found that HAV occurred infrequently in either treatment group, meeting a prespecified criterion for noninferiority for these prophylactic measures. Rates of infection, however, were higher in the vaccine group (8.6%) than in the IGIM group (6.7% overall) and for all HAV study points examined (clinical and subclinical), suggesting that the IGIM performed modestly better than the vaccine in these per-protocol populations (e-Fig. 19.7). Regardless, the ACIP in 2007 updated their recommendations for postexposure prophylaxis to include either hepatitis A vaccine alone or IGIM alone in most exposure circumstances (Table 19.4). The only situation where both vaccine and IGIM were recommended was in a person who shared illicit drugs with a case, and even in this situation, vaccine alone also was an option.

PERSPECTIVES

Detailed studies of early innate and adaptive immune responses to HAV that have been undertaken recently are likely to provide a better understanding of critical responses that lead to the elimination of virus from the host. In addition, through comparative analyses with host responses to another hepatotropic virus—HCV—such studies may help understand why HCV may establish persistent infections in humans whereas HAV never does. A better understanding of HAV virulence mechanisms could lead to the development of novel therapies designed to subvert severe outcomes. As developing countries transition from high endemicity to low endemicity, the need for universal vaccination of the population will become more compelling. The development of an oral vaccine would be of great benefit in this situation.

Perspective

The family *Caliciviridae* is composed of small (27 to 40 nm), nonenveloped, icosahedral viruses that possess a linear, positive-sense, single-stranded RNA (ssRNA) genome. The five genera of the family are *Norovirus*, *Sapovirus*, *Nebovirus*, *Lagovirus*, and *Vesivirus*. The major human pathogens in the family are the noroviruses and sapoviruses, which cause acute gastroenteritis. Important veterinary pathogens include vesiviruses such as feline calicivirus (FCV), which causes a respiratory disease in cats, and lagoviruses such as rabbit hemorrhagic disease virus (RHDV), which causes an often fatal hemorrhagic disease in rabbits. This chapter provides a description of the family *Caliciviridae*, with major emphasis on the noroviruses because of their prominent role in sporadic and epidemic gastroenteritis.¹⁴⁷

HISTORY

The establishment of a viral etiology for gastroenteritis in humans was a decades-long process that was hampered by the fastidious nature of many of these viruses for growth in cell culture.²¹³ Volunteer studies carried out in the 1940s and 1950s in the United States and Japan played a major role in establishing that filterable, nonbacterial infectious agents can cause enteric disease.²¹³ An important advance occurred in 1972 with the discovery of Norwalk virus (NV) by Kapikian et al.²¹⁴ Stool material from a rectal swab obtained from an ill individual involved in a gastroenteritis outbreak that had occurred at an elementary school in Norwalk, Ohio, in October 1968 was administered to adult volunteers as a bacteria-free filtrate and serially passed to other volunteers, inducing acute gastroenteritis in certain individuals.^{112,113} Stool material from these volunteers was then examined for the presence of viruses by the technique of immune electron microscopy (IEM), which involves the direct observation of antigen–antibody complexes by EM.^{11,13,18,214} The fecal filtrate was incubated with prechallenge or convalescent-phase serum from a volunteer who had become ill following ingestion of the filtrate. Figure 20.1 shows the striking difference between the appearance of the small, round virus particles (described as 27 to 30 nm in diameter with a hint of surface structure) after incubation with the prechallenge serum (part A and B) and after incubation with convalescent-phase serum (parts C and D). The increase in visible virus-specific antibodies in the convalescent serum from individuals involved in the original Norwalk outbreak, as well as in volunteers challenged with the virus derived from the outbreak, led to the conclusion that NV was the etiologic agent.²¹⁴ Norwalk virus would become the prototype strain for a large group of related *Norwalk-like viruses* or *small round structured viruses*, known now as the noroviruses.

FIGURE 20.1. Norwalk virus (NV) (genus *Norovirus*) and Sapporo virus (genus *Sapovirus*) in stool material. **A: NV particles in a stool filtrate visualized by immune electron microscopy (IEM). **B:** An aggregate observed after incubation of NV stool filtrate with a 1:5 dilution of volunteer's prechallenge serum. Particles have a light coating of antibody molecules. The amount of antibody present on this aggregate was given a rating of 1 to 2 to 2+ and the serum was given an overall rating of 1 to 2+ on a scale of 1 to 4. **C, D:** Three single particles (**C**) and one individual particle (**D**) observed after incubation of the NV stool filtrate with a 1:5 dilution of the same volunteer's postchallenge convalescent serum. Particles are heavily coated with antibody molecules. At high antibody levels (antibody excess), large aggregates may not be seen. The amount of antibody was given a rating of 4+ and the serum was given an overall rating of 4+ on a scale of 1 to 4. **E:** Sapporo virus particles in stool material visualized by direct electron microscopy (EM). The distinct, hollow cup-like structures are apparent. **F:** Sapporo virus particles after incubation with guinea pig hyperimmune serum. The amount of antibody was given a 1+ rating. **G:** An aggregate observed after incubation of Sapporo virus stool filtrate with guinea pig hyperimmune serum. The amount of antibody was given a rating of 4+ on a scale of 1 to 4. (**A–D** from Kapikian AZ, Wyatt RG, Dolin R, et al. Visualization by immune electron microscopy of a 27-nm particle associated with acute infectious nonbacterial gastroenteritis. *J Virol* 1972;10:1075–1081, with permission. **E–G** from Nakata S, Kogawa K, Numata K, et al. The epidemiology of human calicivirus/Sapporo/82/Japan. *Arch Virol Suppl* 1996;12:263–270, with permission.)**

The techniques used in the discovery of the NV proved instrumental in the subsequent characterization of other fastidious enteric viruses (including human rotaviruses, astroviruses, parvoviruses, enteroviruses, and hepatitis A virus) by an approach that became known as *particle* or *direct virology*.²¹³ Norovirus reference strains such as Hawaii virus (from a family outbreak of gastroenteritis that occurred in Honolulu in 1971) and Snow Mountain virus (from an outbreak in a Colorado resort camp in 1976) were discovered in 1977 and 1982, respectively.^{116,468} In 1976, Madeley and Cosgrove²⁹⁶ reported the presence of “typical” caliciviruses in the stools of infants and young children (2 to 18 months of age), and these viruses showed a striking morphologic similarity to previously characterized animal caliciviruses that were known to exhibit “classical” distinct cup-like depressions on the surface of the virion. That same year, Flewett and Davies¹³⁰ observed similar calicivi-

rus particles in a sample from the intestinal lumen of a child at autopsy and in the feces of a child with gastroenteritis. Chiba et al.⁹⁰ described a “classical” calicivirus, associated with gastroenteritis, in infants and young children living in an infant home in Sapporo, Japan, in 1977. Another virus (later designated Sapporo/82/Japan) that exhibited classical calicivirus morphology was subsequently detected from this same infant home (Fig. 20.1E).³⁴⁰ Hyperimmune serum was raised in guinea pigs against Sapporo/82/Japan virus particles purified from stool material, and IEM was used to establish its antigenic characteristics (Fig. 20.1F and 20.1G, respectively). The Sapporo virus would become the prototype strain for the *Sapporo-like viruses* or *classical caliciviruses*, known now as the sapoviruses.

In the late 1980s, the stool filtrate derived from the Norwalk, Ohio, outbreak was again fed to adults in volunteer studies to obtain adequate quantities of virus particles to

TABLE 20.1 Taxonomic Structure of the *Caliciviridae*

Genus	Species	Representative strain
<i>Norovirus</i> (NoV)	<i>Norwalk virus</i> (NV)	Hu/NoV/GI.1/Norwalk/1968/US
<i>Sapovirus</i> (SaV)	<i>Sapporo virus</i> (SV)	Hu/SaV/GI.1/Sapporo/1982/JP
<i>Lagovirus</i> (LaV)	<i>Rabbit hemorrhagic disease virus</i> (RHDV)	Ra/LaV/RHDV/GH/1988/DE
	<i>European brown hare syndrome virus</i> (EBHSV)	Ha/LaV/EBHSV/GD/1989/FR
<i>Nebovirus</i> (NeV)	<i>Newbury-1 virus</i> (NBV)	Bo/NeV/NBV/Newbury-1/1976/UK
<i>Vesivirus</i> (VeV)	<i>Vesicular exanthema of swine virus</i> (VESV)	Po/VeV/VESV/VESV-A48/1948/US
	<i>Feline calicivirus</i> (FCV)	Fe/VeV/FCV/F9/1958/US

The cryptograms are organized as follows: host species from which the virus was obtained/genus/species (or genogroup)/strain name/year of occurrence/country of origin. Abbreviations for the host species are Fe, feline; Ha, Hare; Hu, Human; Po, Porcine; Ra, Rabbit. Country abbreviations are DE, Germany; FR, France; JP, Japan; US, United States.

characterize the viral genome, a major advance by Jiang et al¹⁹⁹ that established the classification of Norwalk virus as a member of the *Caliciviridae*. The complete RNA genome sequences of Norwalk virus and the closely related Southampton virus were determined and found to be organized into three major open reading frames (ORF1, -2, and -3) with a polyadenylated 3' end^{176,202,253,254} (see Genome Structure and Organization). The ORF1 was shown to encode a large polypeptide that was proteolytically processed into the mature nonstructural proteins.^{273,276} The ORF2 encoded the major capsid protein, VP1, and ORF3 encoded a minor structural protein, VP2. The human noroviruses initially segregated into two major phylogenetic groups within what would become the genus *Norovirus* of the *Caliciviridae* that were designated as genogroups I (GI) and II (GII), with NV belonging to GI and the Hawaii and Snow Mountain viruses belonging to GII.^{266,487} In addition, sequence analysis of the “classical” caliciviruses confirmed that they were distinct from the noroviruses, ultimately forming a separate genus, *Sapovirus*, within the *Caliciviridae*.^{252,274,309}

CLASSIFICATION

Members of the virus family *Caliciviridae* have a virion protein, genome (VPg)-linked, positive-sense RNA genome that is polyadenylated and surrounded by a nonenveloped, icosahedral capsid of 27 to 40 nm in diameter. The capsid is constructed predominantly from a major structural protein, VP1, of approximately 60,000 D. The five genera of the family *Caliciviridae*—*Norovirus*, *Sapovirus*, *Lagovirus*, *Nebovirus*, and *Vesivirus*—each represent a distinct phylogenetic clade in the family^{92,152} (e-Fig. 20.1). Within each genus, one or more species has been defined based primarily on genetic relatedness, and the current taxonomic structure of the *Caliciviridae* is shown in Table 20.1. It is possible that additional genera will be established, following characterization of the

unique genomes of Tulane virus (simian),¹²⁸ St. Valérian virus (porcine),²⁵¹ and Bayern virus (avian)⁵⁰⁹ (e-Fig. 20.1). Below the level of species in certain genera (*Norovirus* and *Sapovirus*), provisional genetic typing systems (consisting of genogroups subdivided into genetic clusters or genotypes) have proven useful in epidemiologic studies (see Molecular Epidemiology).

VIRION STRUCTURE

Calicivirus virions exhibit $T = 3$ icosahedral symmetry. The capsid contains 90 dimers of the VP1 capsid protein that form a shell from which 90 arch-like capsomeres protrude at the local and strict twofold axes.^{86,381,382,384} These arches are arranged in such a way that 32 large hollows are seen at the icosahedral five- and threefold positions, and these hollows are seen as cup-like structures on the surface of caliciviruses (*calici* is derived from the Latin word *calyx*, or “cup”). Electron cryomicroscopy and computer image processing studies of representative caliciviruses show subtle variation in the capsid structures that are consistent with their differences in appearance by negative-stain EM, which can range from a feathery appearance (many noroviruses, such as Norwalk virus in Fig. 20.1A) to the presence of sharply defined “cups” (many sapoviruses, such as Sapporo virus in Fig. 20.1E and the vesiviruses).^{86,383}

Self-assembly of the norovirus VP1 into virus-like particles (VLPs) is an efficient process and does not require RNA²⁰¹ or the minor capsid protein, VP2.^{256,263} This feature has been especially useful in the study of the fastidious caliciviruses, because recombinant (r) VLPs expressed in the baculovirus system have served as a surrogate for native virions.^{154,201,203} The NV rVP1 (180 copies) characteristically self-assembles into 38-nm particles with $T = 3$ symmetry, but it can form smaller VLPs (23 nm) with $T = 1$ symmetry composed of 60 copies of VP1.⁴⁹⁸

The atomic structure of the Norwalk rVLP has been determined by x-ray crystallography.³⁸² These structural studies

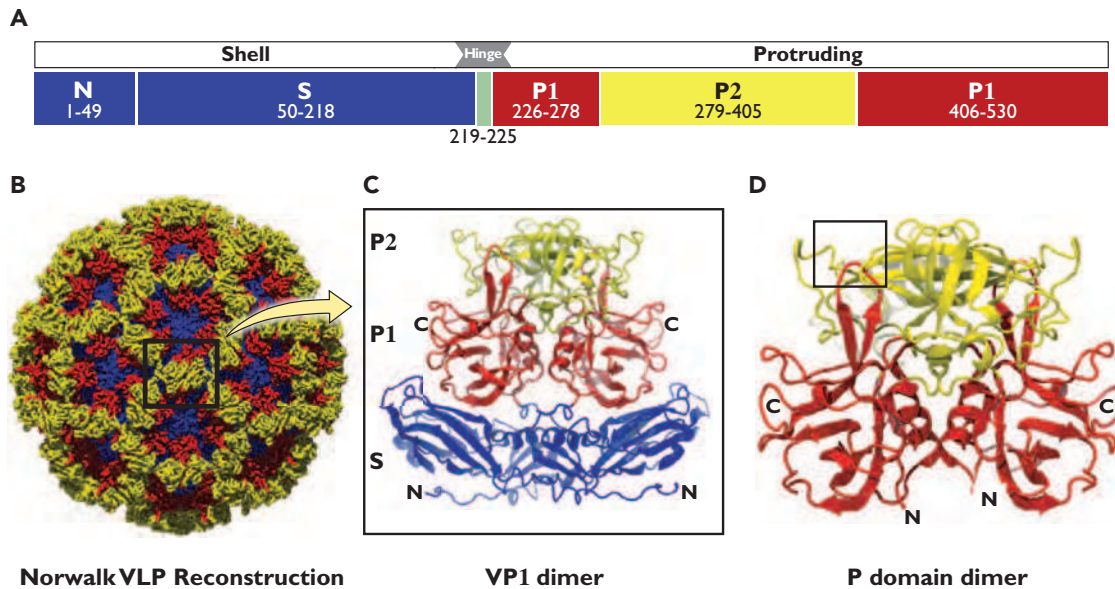

FIGURE 20.2. Organization of the norovirus major capsid protein, VP1. **A:** The Norwalk virus major capsid protein VP1 is 539 amino acids (aa) in length and is organized into two major parts, shell (S) and protruding (P), connected by a hinge (H) region. The aa borders of the defined domains are N-terminal (N) arm, 1 to 49; S, 50 to 218; hinge, 219 to 225; P1, 226 to 278 and 406 to 530; and P2, 279 to 405. (Adapted from Prasad BV, Hardy ME, Dokland T, et al. X-ray crystallographic structure of the Norwalk virus capsid. *Science* 1999;286:287–290.) **B:** Model of the T = 3 Norwalk virus whole capsid, determined at 3.4-Å resolution.³⁸² The capsid is composed of 90 dimers of VP1, with the S, P1, and P2 domains shown in blue, red, and yellow, respectively. The box highlights the arrangement of a VP1 dimer as it is displayed on the surface of the virion. **C:** Three-dimensional ribbon representation of a VP1 dimer derived from x-ray crystallography studies of Norwalk virus recombinant virus-like particles (rVLPs) at 3.4 Å, showing the presentation of the P2 domain at the top of an arch supported by two P1 domain “arms”.³⁸² The S domain forms the internal scaffold of the virion that surrounds the RNA genome and positions the arch to the virion surface. The N-terminus (N) and C-terminus (C) of the VP1 are indicated. **D:** Three-dimensional ribbon representation of a P domain-only dimer, determined at 1.4-Å resolution.⁹¹ The box highlights the location of a histo-blood group antigen (HBGA) carbohydrate binding site mapped within the P2 domain (see Fig. 20.7). (Images provided by B. V. V. Prasad.)

have defined two major domains in the VP1—the shell (S) and the protruding (P) arm (Fig. 20.2). The S domain forms the inner part of the capsid that surrounds the RNA genome and maintains the icosahedral contacts of the T = 3 structure, and the P domain forms the arch-like protrusions that emanate from the shell and contain the dimeric contacts.³⁸² The amino acid residues that correspond to the S and P subdomains in the NV VP1 (530 amino acids in length) are diagrammed in Figure 20.2A. A ribbon model of the VP1 dimeric subunit derived from the crystallographic structure of the capsid shows a more detailed view of these domains and their interactions (Fig. 20.2B, C). The NH₂-terminal (N) arm, located within the S domain, consists of residues 1 to 49 and faces the interior of the capsid. The part of the S domain that forms a classic eight-stranded antiparallel β -sandwich fold consists of amino acids (aa) 50 to 225 (which includes a flexible hinge). The entire S domain (aa 1 to 225) corresponds to the N-terminal region of the capsid protein that is relatively conserved among noroviruses in sequence comparisons. The P domain, which is linked to the S domain through a flexible hinge (aa 219 to 225), corresponds to the C-terminal half of the VP1, which is more variable in amino acid sequence. The P domain is divided into the P1 subdomain, encompassing aa 226 to 278 and 406 to 520, and the P2 subdomain, encompassing aa 279 to 405. The P1 subdomains form the sides of

the arch of the capsomeres and position the highly variable P2 subdomain at the top of the arch. In the dimeric form of the capsid protein, two P2 subdomains form what appears to be a bilobed structure at the surface of the virion. The exposure of the variable P2 region on the surface is consistent with its role in the formation of a major antigenic site and in receptor binding.^{10,47,85,86,107,110,172,178,185,221,271,281,348,382,398,459,497} It has been proposed that the highly conserved S domain may function as an icosahedral scaffold with the N-terminal arm providing a switch to facilitate the appropriate curvature, and that the P domain may be a replaceable module for conferring strain differences and antigenic specificity.^{85,86,382} Structural studies of other caliciviruses have shown a similar organization, with an internal shell domain serving as the scaffold for the more variable protruding domain.^{85,220}

Knowledge of the capsid structure has informed study of capsid assembly and facilitated the expression of subviral forms of the capsid that have proven useful in several areas of research (e-Fig. 20.2).⁴⁶⁰ The extreme N-terminus of the NV VP1 protein (first 20 aa) was not required for the assembly of native-sized 38-nm VLPs with T = 3 symmetry.³⁶ Expression of the NV VP1 S region alone (beginning with the extreme N-terminus of the VP1 and including amino acid residues 1 to 227) resulted in the formation of smooth particles (designated “S” particles in e-Fig. 20.2) of approximately 30 nm in diameter.³⁶

Although initial expression of the NV P region alone did not yield VLPs in baculovirus or bacterial systems,^{36,458} the native P domain from NV and other noroviruses formed *P dimers* that were recognized by antibodies and carbohydrates similarly to intact VLPs.⁴⁵⁸ The ability to produce rapidly P dimers (and mutagenized forms) accelerated structure and function studies of the norovirus capsid protein.^{61,463,464,465} Further genetic engineering to include a four to seven arginine-rich sequence at the C-terminus of the P domain resulted in the generation of small, subviral particles termed *P particles* that were assembled from 12 dimers of the P domain and that showed T = 1 symmetry.^{460,463} (e-Fig. 20.2). Recently, expression of the P domain with a further modified terminus allowed the production of *small P particles*.⁴⁵⁷

GENOME STRUCTURE AND ORGANIZATION

Caliciviruses have a linear, single-stranded, positive-sense RNA genome (ranging from approximately 7.3 to 8.5 kb [kilobases]

in length) (Fig. 20.3A). Genomes characteristically begin with a 5' end terminal pGpU sequence that is covalently linked to a small protein, VPg. A short conserved region (CR) at the 5' end is repeated internally in the genome near the beginning of a subgenomic-sized RNA transcript that is co-terminal with the 3' end of the genome.^{179,254,324,331,344} The nonstructural proteins are encoded beginning near the 5' end of the genome, and the structural proteins (VP1 and VP2) are encoded toward the 3' end of the genome in the region corresponding to a subgenomic RNA. Calicivirus genomes are organized into two or more major ORFs, depending on the genus. The noroviruses and vesiviruses encode the VP1 structural protein in a separate ORF (ORF2), whereas sapoviruses, lagoviruses, and neboviruses encode a VP1 that is contiguous with the large nonstructural polyprotein in ORF1 (Fig. 20.3B). All caliciviruses have a relatively small ORF near the 3' end that encodes the minor structural protein, VP2. The VP2 is variable in size (12,000 to 29,000 D) and sequence identity among the caliciviruses.^{65,418} Murine norovirus genomes analyzed thus far contain a unique conserved ORF (ORF4).⁴⁶⁷ with an encoded protein of 23,800 D

A Genome Organization

B Reading Frame Usage

C Gene Order and Cleavage Sites

FIGURE 20.3. Comparative features of calicivirus genomes. **A:** The positive-sense RNA genome is covalently linked to a virion protein genome (VPg) at the 5' end and polyadenylated at the 3' end. Nonstructural proteins are encoded beginning from the 5' end of the genome and the structural proteins are encoded toward the 3' end. A conserved region (CR) of nucleotide sequence is shared between the 5' end of the viral genome and the 5' end of an abundant subgenomic RNA species produced during replication that serves as a template for translation of the viral structural proteins. **B:** Calicivirus genome organization. Calicivirus genomes are organized so that the major capsid protein coding sequence is either in frame or not with the upstream nonstructural protein sequence. The genomic organization and reading frame usage are shown for representative strains in the genera *Lagovirus* (Ra/LaV/RHDV/GH/1988/DE, GenBank Accession Number M67473), *Nebovirus* (Bo/NeV/NBV/Newbury-1/1976/UK, GenBank Accession Number DQ013304), *Sapovirus* (Hu/SaV/Manchester/1993/UK, GenBank Accession Number X86560), *Norovirus* (Hu/NoV/Norwalk/1968/US, GenBank Accession Number M87661), and *Vesivirus* (Fe/VeV/FCV/F9/1958/US, GenBank Accession Number M86379). **C:** A large polyprotein (encoded in open reading frame 1 [ORF1]) is translated from the viral RNA genome, and it is processed into precursors and final products by a virus-encoded protease. The proteolytic processing strategy varies among the caliciviruses, but all viruses encode domains for at least seven protein functions indicated here as nonstructural (NS) proteins NS1 through NS7.⁴³⁴ An extra cleavage site is present in the ORF1 of caliciviruses in which the capsid protein sequence is in frame with the nonstructural polyprotein encoded in ORF1. Cleavage at this site is thought to release the VP1 from the polyprotein so that the RNA-dependent RNA polymerase (NS7) can adopt an active conformation early in the replicative cycle. A cleavage site unique to the vesiviruses is present to release the leader of the capsid protein (LC) from a capsid precursor encoded in ORF2.⁴³⁸ Mapped cleavage sites conserved and utilized among all calicivirus genera are indicated with a dark arrow; cleavage sites that vary in utilization among the family are indicated with a light arrow.^{238,273,276,358,359,434,435,438,506}

(designated VF-1) that has been implicated in modulation of the host innate immune response *in vivo*.³¹⁸

Viral Proteins

Structural Proteins

Three proteins are found in mature calicivirus virions: VP1, VP2, and VPg.⁴³⁶ The VP1 (~60,000 D), which is the major structural protein of the virus, is present in 180 copies (90 dimers) per virion.³⁸³ The predominance of VP1 in the formation of the viral capsid structure (see Virion Structure) is consistent with its critical role in determining the antigenic phenotype of the virus and its interactions with host cells.

The VP2 (12,000 to 29,000 D) is considered a minor structural protein because it is present in only one to two copies per virion, and its function is unknown.^{145,146,436} The ablation of VP2 expression in an infectious FCV complementary DNA (cDNA) clone by the introduction of a stop codon in its reading frame did not abolish RNA replication; however, infectious virions could not be recovered without an intact VP2.⁴³³ Although VP1 can self-assemble into rVLPs independently of the presence of VP2,^{256,263} the presence of VP2 may increase the efficiency of VP1 expression and enhance the stability of rVLPs generated in the baculovirus expression system.³⁵ Evidence for a direct interaction between the VP1 and VP2 capsid proteins has been reported for both NV^{74,145,146} and FCV,^{108,211} further suggesting a role in particle maturation or stability.

The VPg is covalently linked to the genomic and subgenomic RNA in infected cells,^{120,180} and is a minor component in virions at an estimated one or two copies per particle.^{410,436} Although the VPg is present in virions, it likely functions primarily as a nonstructural protein during replication (see Nonstructural Proteins).

Nonstructural Proteins

Caliciviruses derive their mature nonstructural proteins (designated here as NS1 through NS7) by proteolytic cleavage of a large polyprotein encoded in ORF1 (Fig. 20.3C). The length of the noncleaved polyprotein precursor is approximately 200,000 D (excluding the in-frame VP1 capsid protein sequences of the lagoviruses, neboviruses, and sapoviruses). This large precursor has never been observed, most likely because proteolytic processing is rapid and co-translational.^{273,276,439} The proteolytic cleavages are mediated by a virus-encoded cysteine proteinase (NS6^{Pro}).⁵⁰ The location of the cleavage sites in the ORF1 polyprotein that define the borders of the final nonstructural protein cleavage products has been determined for calicivirus strains representing the genera *Norovirus*,^{34,273,276,434} *Vesivirus*,⁴³⁵ *Lagovirus*,^{238,506} and *Sapovirus*.³⁵⁹ Some variation is seen among the proteolytic processing strategies, but the overall gene order of the calicivirus nonstructural proteins is conserved. The lagoviruses, represented by RHDV, have the highest number (six) of mapped cleavage sites. The polyprotein of RHDV is cleaved at these six sites to release seven final products (designated as NS1 through NS7 in Fig. 20.3C and Table 20.2). Five cleavage sites for the norovirus ORF1 polyprotein (represented by Southampton virus) have been mapped that would release six mature products.^{273,276} The noroviruses differ from the lagoviruses in that a protease cleavage site has not been directly mapped in the extreme N-terminal protein, although evidence suggests that additional processing (or modification) of the protein can occur in cells.^{419,434} The vesivirus cleavage

map (represented by FCV) contains five mapped cleavage sites to release six mature nonstructural proteins, and each cleavage event is essential in the virus replication cycle.⁴³⁵ The vesiviruses show yet another variation in processing, in that no evidence exists for efficient viral protease-mediated cleavage between the Pro and polymerase (Pol) proteins, even in virus-infected cells.^{306,357,435,439} In addition, vesiviruses bear a unique cleavage site in a capsid protein precursor protein that is processed by NS6^{Pro} to release the leader of the capsid (LC) and the major capsid protein, VP1^{438,470} (Fig. 20.3C). The predicted nonstructural protein cleavage map of human sapovirus strain, Mc10, shows an overall similarity with that of the vesiviruses.³⁵⁹ Sapoviruses (and other caliciviruses in which the capsid region is in frame with the nonstructural polyprotein) bear an additional protease cleavage site in the ORF1 polyprotein between the polymerase and capsid coding regions. A number of stable precursor proteins have been described also for the caliciviruses, and it is likely that these proteins have defined functions in replication.^{34,39,93,238,325,326,434,435}

The calicivirus dipeptide cleavage recognition sites are consistent with those described for the picornavirus 3C cysteine proteinase.¹⁷⁴ The calicivirus cleavage sites identified thus far have either a negatively charged glutamic acid (E) or polar glutamine (Q) in the first position (designated P1). More variation exists within the second position of the dipeptide cleavage site (designated P1'). Studies of the calicivirus proteinase substrate specificity have shown some tolerance in the P1' position at certain cleavage sites.^{174,438,505} The conformation of the protein surrounding the dipeptide recognition site is also important for efficient cleavage by the proteinase.^{174,439}

The availability of proteolytic cleavage maps for the calicivirus nonstructural polyproteins has enabled studies that elucidate the functions and structures of individual proteins.¹⁷⁵ Biochemical studies first confirmed enzymatic activities in calicivirus proteins corresponding to an NTPase (NTPase or NS3^{NTPase}),³⁰⁰ a chymotrypsin-like cysteine proteinase (Pro or NS6^{Pro}),⁵⁰ and an RNA-dependent RNA polymerase (Pol or NS7^{Pol}).⁴⁷⁹ The three-dimensional structures for the latter two enzymes have been reported. The norovirus Pro shares structural similarities with classical chymotrypsin-like serine proteases^{188,189,339,518} (Fig. 20.4A). A cleft containing the active site catalytic residues (His 30, Glu 54, and Cys 139 for Norwalk virus) involved in substrate cleavage is located between two domains. The N-terminal domain (blue) starts with an α -helix followed by a five-stranded twisted antiparallel β -sheet. The structure of this domain contains features of both the simpler four-stranded β -sheet found in the N-terminal domain of picornaviral 2A proteinases and the more commonly found complete β -barrels observed in the N-terminal domains of most chymotrypsin-like proteinases. The C-terminal domain (red) adopts the structure of a classical six-stranded β -barrel found in a wide range of viral and nonviral chymotrypsin-like proteinases. Co-crystallization of the protease with an active site-directed peptide inhibitor (acetyl-Glu-Phe-Gln-Leu-Gln-propenyl ethyl ester) has given detailed insight into the interaction of substrate with the catalytic residues such as Cys 139 (the active site nucleophile) within the cleft¹⁸⁹ (Fig. 20.4B). The norovirus RNA-dependent RNA polymerase has a classical "right hand" (finger, thumb, and palm) organization,^{346,347,517} with the C-terminus of the protein positioned in the active site cleft (Fig. 20.5A). Modeling of the

interaction of Pol with an RNA template in the presence of manganese and cytidine triphosphate (CTP) shows that the initiation of RNA synthesis occurs within the active site cleft (Fig. 20.5B–D). Binding of the primer/template RNA duplex displaces the C-terminal tail away from the active site, allowing the central helix of the thumb domain to position itself for interaction with the primer strand and minor groove of the primer–template duplex.⁵¹⁷ Two divalent metal ions (likely

Mg²⁺ in cells) help mediate catalysis by forming coordination bonds with three highly conserved aspartic acid residues and the nucleoside triphosphate (NTP). After nucleotidyl transfer has occurred, the pyrophosphate is released from the enzyme. The primer–template duplex is predicted to translocate in a manner that places the newly incorporated nucleotide into the same position as that of the 3' end of the primer strand immediately prior to nucleotidyl transfer. This translocation process

Norovirus Proteinase

FIGURE 20.4. Structure of the norovirus proteinase. **A:** Three-dimensional ribbon representation of the Norwalk virus protease structure resolved at 1.5 Å shows that it adopts the conformation of a classical serine protease, in which a cleft containing the enzymatic active site is located between two β -barrel domains. The active site is positioned at the opening of the cleft and composed of residues His 30, Glu 54, and Cys 139 (the *catalytic triad*). The conformation of the loops and β -strands are thought to play a role in positioning the active site residues for proteolysis. **B:** Modeled interaction of Norwalk virus protease with an inhibitor that blocks proteolysis.^{188,189,339,518} (Images provided by K. Ng.)

provides the space needed to form the binding site for the next incoming nucleoside triphosphate.

Although the gene order of the nonstructural proteins and strong structural and functional homology in the Pro and Pol enzymes suggest a common ancestor for the caliciviruses and picornaviruses,³⁴² it is striking that several proteins encoded in the calicivirus ORF1 share little or no detectable sequence

relatedness with the picornaviruses. These include the extreme N-terminal proteins NS1 and NS2 (corresponding in gene order to the picornavirus 2A and 2B proteins), the NS4 (corresponding to the picornavirus 3A protein), and the NS5 (corresponding to the VPg). Although the roles of these proteins in replication require further investigation, evidence for some functional homology with the picornaviruses has been

Norovirus RNA-dependent RNA Polymerase

FIGURE 20.5. Structure of the norovirus RNA-dependent RNA polymerase. **A:** The norovirus RNA-dependent RNA polymerase adopts the classic “right hand” structure characteristic of polynucleotide polymerases as shown in this stick model. The fingers (blue) and palm (green) domains form a rigid unit, while the thumb (red) domain is flexible and can assume either a “closed” or “open” conformation. An N-terminal domain bridges the fingers and thumb domains. When the polymerase is unbound to template, the C-terminal end of the protein appears to lie within the active site cleft.³⁴⁷ **B–D:** The front, top, and side views, respectively, of the Norwalk RNA polymerase bound to a primer–RNA duplex, cytidine triphosphate (CTP), and metal divalent cation, Mn²⁺.^{24,346,347,517} (Images provided by K. Ng.)

proposed.^{25,129,422} A summary of the calicivirus nonstructural proteins and their known properties is shown in Table 20.2.

STAGES OF REPLICATION

Replication Strategy

The replication strategy elucidated thus far for the caliciviruses shares many features with those of other positive-strand RNA viruses (Fig. 20.6). Caliciviruses attach and enter the cell, the

RNA genome is released, and translation of the genome occurs via the host cell machinery. Certain newly translated viral proteins interact with the host cell to establish defined sites of virus replication (characteristically involving reorganized intracellular membranes), while other proteins function as replicative enzymes. Newly synthesized positive-strand RNA genomes are covalently linked to VPg and packaged into virions that are released from lysed cells. The replication cycle of a calicivirus is rapid: new viral progeny can be detected within hours after infection.

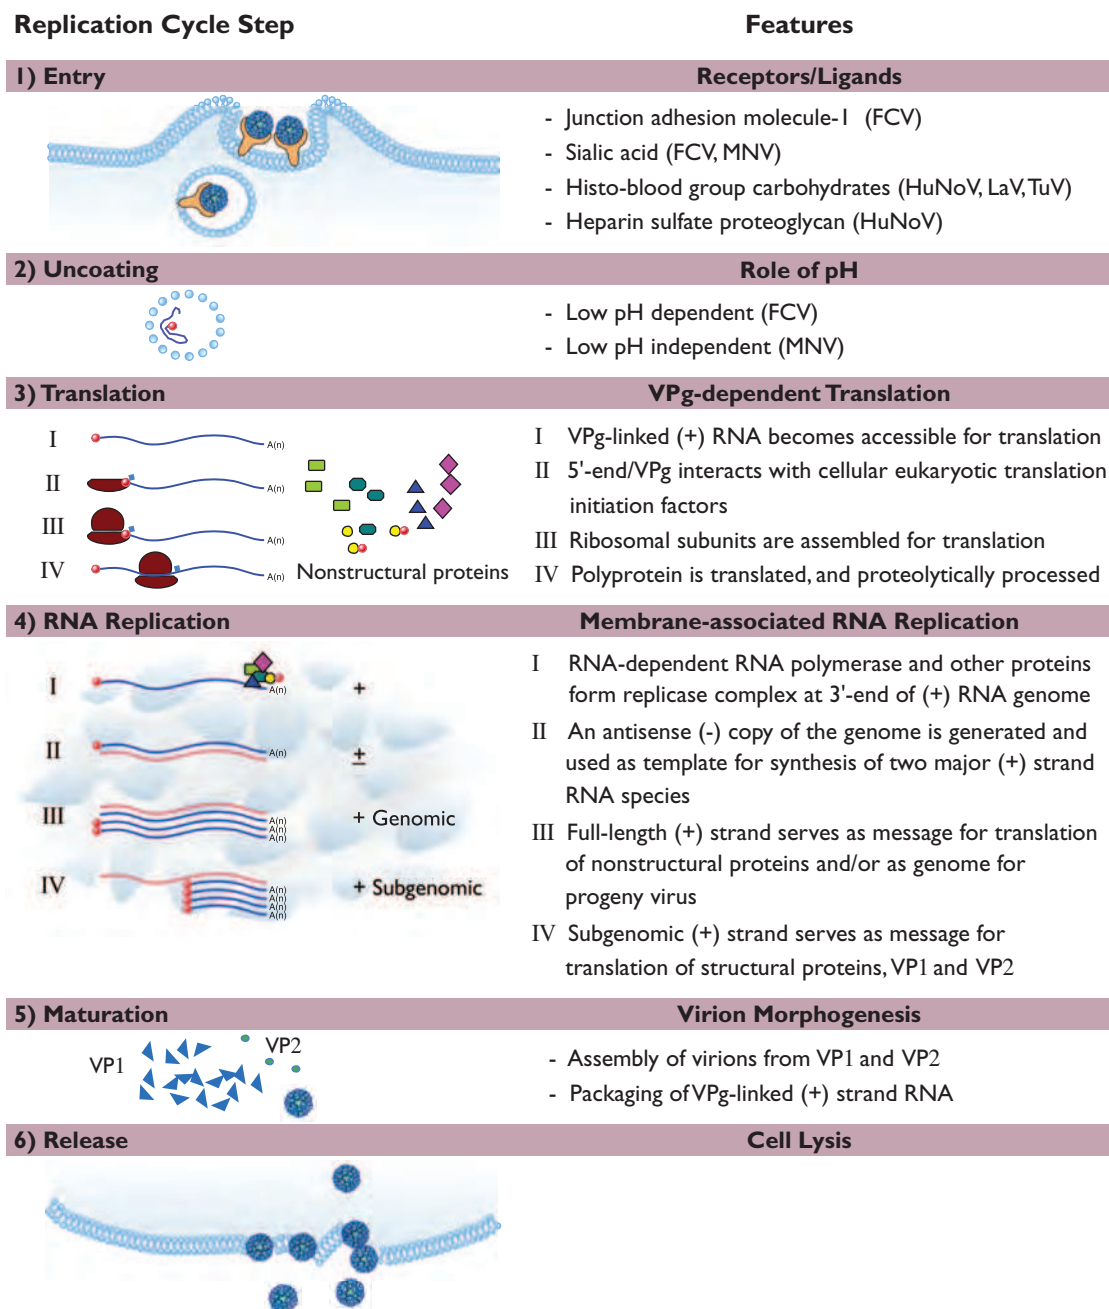

FIGURE 20.6. Schematic diagram of the proposed replication strategy of the caliciviruses. Consistent with other positive-strand RNA viruses, the replication cycle of a calicivirus involves the following stages: **(1)** entry, **(2)** uncoating, **(3)** translation, **(4)** RNA replication, **(5)** maturation, and **(6)** release, as reviewed in the text. FCV, feline calicivirus; LaV, lagovirus; MNV, murine norovirus; HuNoV, human norovirus; TuV, Tulane virus.

Reverse genetics systems have been developed for several caliciviruses, including FCV,⁴³² porcine enteric calicivirus,⁷⁷ Tulane virus,⁴⁹² RHDV,²⁷⁷ and murine norovirus,^{83,489,515} based on the construction of infectious full-length cDNA clones of the viral genome. Murine norovirus is presently the only norovirus that grows efficiently in cell culture,⁵⁰⁷ making this virus an important model.⁵⁰⁸ Human norovirus infectious cDNA clones have remained elusive in the absence of a fully permissive cell culture system to verify recovery of virus, but replication in cells can be studied following expression of proteins from full-length cDNA clones^{21,219} or in stable RNA replicon-bearing cell lines.⁷⁹

Mechanism of Attachment

Calicivirus virions must first interact with the host cell. Carbohydrates, including those present on various histo-blood group antigens (HBGAs), have been implicated in the binding of a number of calicivirus strains to cells^{245,301,403,443,455,462,516} (Fig. 20.6). Structural studies have verified that the norovirus VP1 interacts with HBGA carbohydrates^{61,91} (Fig. 20.7). Receptor recognition is essential for the caliciviruses, as transfection of infectious calicivirus RNA into nonpermissive cells (i.e., those that cannot be infected with virions) allows replication and recovery of infectious progeny virus.^{162,245,298} The junction adhesion molecule-1 (JAM-1), an immunoglobulin-like cellular membrane protein, has been identified as a functional receptor for FCV,²⁹⁹ making this the first experimentally verified cellular receptor in the family. Structural and modeling studies have shown that FCV interacts with feline (f) JAM-1 through binding of the P2 domain of the capsid to the distal membrane domain (D1) of fJAM-1^{37,38,363} (e-Fig. 20.3).

Nearly all norovirus VLPs bind to one or more HBGA carbohydrates, and as noted earlier, structural studies have defined interactions with certain HBGA saccharides at the amino acid level⁶¹ (Fig. 20.7). A correlation was found between susceptibility to Norwalk virus infection in adult volunteers and HBGA secretor status, which is linked to the *FUT2* gene²⁶⁹ (see Cell and Tissue Tropism). A similar pattern of genetic susceptibility to RHDV (lagovirus) infection in rabbits was associated with genes involved in the modification of HBGAs, indicating a role for blood group carbohydrates in host cell recognition by lagoviruses.¹⁶¹ Experiments to verify that HBGAs can serve as a functional receptor for the noroviruses have been unsuccessful, hampered in part by the unavailability of a permissive cell culture system. Expression of the human *FUT2* gene product (fucosyltransferase-2) in nonpermissive cells enhanced binding of Norwalk virus VLPs to cells *in vitro* but did not render them permissive for the virus.¹⁶²

Mechanism of Entry and Intracellular Trafficking

Variation has been noted among caliciviruses in their requirements for entry into cells and subsequent infection. Feline calicivirus replication was inhibited by chloroquine, a reagent that raises lysosomal pH, indicating dependence on a low pH step during entry.^{244,444} In contrast, murine norovirus (strain MNV-1) was not dependent on the acidification of endosomes for infectivity.^{143,373} Feline caliciviruses use clathrin-mediated endocytosis for entry into mammalian cells,⁴⁴⁴ whereas MNV-1 apparently does not enter via clathrin- or caveolin-mediated pathways.^{143,373} An endocytic pathway was proposed for MNV-1 entry that likely involves cholesterol-sensitive lipid rafts and dynamin II (at least in RAW264.7 cells).^{143,373,374}

FIGURE 20.7. Interaction of representative norovirus VP1 dimers with H carbohydrates from histo-blood group antigens (HBGAs). For both GI.1 and GII.4 noroviruses, HBGA carbohydrates interact with the distal surface of the capsid, but differences in these interactions have been noted. The Norwalk virus (GI.1) carbohydrate binding site contains residues that project from a well-structured antiparallel β -sheet near the P domain dimeric interface and favors a precise and limited recognition of a terminal Gal-Fuc or Gal-acetamido combination. In contrast, the VA387 (GII.4) binding site is formed by residues located in two surface-exposed loops near the P domain dimeric interface that broadly recognize a terminal fucosyl moiety. (Courtesy of B. V. V. Prasad with data adapted from Cao S, Lou Z, Tan M, et al. Structural basis for the recognition of blood group trisaccharides by norovirus. *J Virol* 2007;81:5949–5957; and Choi JM, Hutson AM, Estes MK, et al. Atomic resolution structural characterization of recognition of histo-blood group antigens by Norwalk virus. *Proc Natl Acad Sci U S A* 2008;105:9175–9180.)

Uncoating

The uncoating events that allow the calicivirus positive-sense RNA genome to become accessible to the cellular translational machinery have not been defined. Uncoating is a rapid process: MNV genome was released within 1 hour after infection.³⁷⁴ Binding to the cellular receptor induces a conformational change in the capsid of FCV, suggesting that uncoating may, in part, be receptor binding mediated.³⁷ FCV infection is associated with an increase in permeability of the host cell membrane soon after virus entry via clathrin-coated endosomes and exposure to low pH.⁴⁴⁴ It was proposed that this acidification process might change the conformation of the FCV virion structure to facilitate release of the viral RNA.⁴⁴⁴ Analysis of norovirus (Norwalk) VLPs by mass spectrometry has shown that they are stable under acidic conditions; a disassembly model has been proposed in which T = 3 particles (containing 180 copies of VP1) disassociate into predominantly dimers in the presence of alkaline conditions.⁴²⁶

Translation

Calicivirus genomic RNA in virions requires the presence of the covalently linked VPg protein in order to establish an infection after release (or transfection) into cells.⁵⁸ The initiation of translation of the incoming positive-strand genome is likely mediated through interactions of the VPg protein with the cellular translation machinery.^{82,103,148,165} Calicivirus replication is associated with an inhibition of host cell translation, and the viral proteinase (NS6^{Pro}) has been shown to cleave certain cellular proteins involved in translation, which may, in part, give the viral RNA a competitive advantage.²⁵⁰ The ORF1 of the virus is translated first to produce a large polyprotein, which is processed rapidly into precursors and products by NS6^{Pro} at several essential cleavage sites.⁴³⁵ Some of these nonstructural proteins and their precursors function to set up replication sites within the host cell,^{25,194} while others (such as the RNA-dependent RNA polymerase, NS7^{Pol}) play a role in replication of the viral RNA (Table 20.2).

An abundant VPg-linked subgenomic positive-strand RNA serves as a bicistronic message for translation of the structural proteins VP1 and VP2,^{179,344} and the regulation of translation of VP2 from the subgenomic RNA (translated at approximately 20% of the levels of VP1) was mapped to an upstream RNA sequence element in the VP1 coding region of approximately 70 nucleotides designated as the termination upstream ribosomal binding site (TURBS).^{322,323} The TURBS site contains two motifs, one of which mediates base pairing between the viral subgenomic messenger RNA and the cellular 18S ribosomal subunit.³²² This interaction may function as a “tether,” positioning the ribosome for immediate reinitiation of translation following termination of translation of the VP1 gene.^{291,292}

Replication of Genomic Nucleic Acid

As with all other positive-strand RNA viruses, the replication of calicivirus RNA is associated with host cell membranes.¹⁵⁵ A marked rearrangement of intracellular membranes occurs, and evidence exists for the initiation of RNA replication in a perinuclear site that contains membranes associated with endoplasmic reticulum, trans-Golgi network, and endosomal membrane markers.^{25,194} The initiation of synthesis of an anti-sense (negative)-strand RNA from the genomic RNA template occurs beginning at the 3′ end of the genomic positive-strand

RNA and likely involves interactions with cellular proteins.¹⁶⁶ The negative-strand RNA, in turn, serves as a template for transcription of two major positive-strand RNA species corresponding to the full-length genome (genomic RNA) and the approximately terminal one-third of the genome toward the 3′ end (subgenomic RNA).³⁴⁴

The calicivirus RNA genome bears conserved regions of secondary structure,^{292,378,429} and functional RNA regulatory elements have been mapped both internally and near the ends of the genome.²⁶ Transcription from the start site for the subgenomic RNA species on the negative-strand template (nt 5,296 of RHDV) was found to require an upstream sequence of 50 nt for full polymerase activity in *in vitro* studies,³³¹ consistent with its role in the formation of a subgenomic promoter. The corresponding region of MNV was mapped also as bearing a promoter for subgenomic RNA synthesis from the negative-strand template.⁴²⁹

Assembly

A two-stage process has been proposed for the maturation of calicivirus (FCV) particles.²³⁷ The first stage involves the rapid aggregation and assembly of capsid precursor proteins into 5S subunits, which then pass through several intermediate forms (with varying stability) to form stable 15S subunits. The second stage involves the association of 15S subunits with newly synthesized RNA genomes to form infectious particles (that sediment at 170S). Protein–protein interactions have been detected between the FCV VPg (covalently linked to the RNA genome) and the capsid precursor as well as between the RNA-dependent RNA polymerase NS7^{Pol} and the capsid precursor, suggesting that these interactions may be related to packaging of the newly synthesized RNA into the viral capsid.²¹¹ In addition, successful assembly of the infectious FCV virions was linked to an efficient expression of the virus minor capsid protein, VP2.⁴³³

The VPg-linked genomic and subgenomic positive-strand RNA species are found in FCV and RHDV particles of distinct densities, indicating that they are not packaged together in the same virion.^{324,343} The incorporation of subgenomic RNA into the lower-density (LD) particles suggests that a packaging signal is located within the 3′ terminal 2,400 nucleotides of the genome. It has been suggested that LD particles (which would not be infectious) may be associated with FCV strains of higher virulence, but their function, if any, in the virus life cycle is unknown.³⁴³

Release

Calicivirus-infected cells undergo lysis, and it is presumed that the majority of progeny viruses are released during this process. The triggering of apoptosis has been associated with calicivirus infection both *in vitro*^{7,49,135,341,437} and *in vivo*,^{12,84,208,223,334,337,386,472} and apoptotic changes in cellular membranes may be one of the mechanisms by which cells lyse and release viral particles.

PATHOGENESIS AND PATHOLOGY

Caliciviruses cause a broad range of diseases in many different animal hosts (Table 20.3). This section will focus on the noroviruses, but there are important common themes in pathogenesis shared by all caliciviruses. Illnesses range from

TABLE 20.3 Pathogenesis and Disease Manifestations of Representative Calicivirus Strains

Calicivirus strain	Genus	Host	Site of replication ^a	Clinical disease ^b
Norwalk virus	Norovirus	Human	Enteric	Gastroenteritis
Jena virus	Norovirus	Cattle	Enteric	Gastroenteritis
Murine norovirus-1 (MNV-1)	Norovirus	Mouse	Enteric, lymphoid cells	Fulminant organ dysfunction ^c
Pistoia virus	Norovirus	Lion	Enteric	Hemorrhagic enteritis ^d
Canine norovirus	Norovirus	Dog	Enteric	Gastroenteritis
Swine 43	Norovirus	Pig	Enteric	Not established
Sapporo virus	Sapovirus	Human	Enteric	Gastroenteritis
Porcine enteric calicivirus (Cowden)	Sapovirus	Pig	Enteric	Gastroenteritis
Mink enteric calicivirus	Sapovirus	Mink	Enteric	Gastroenteritis
Rabbit hemorrhagic disease virus	Lagovirus	Rabbit	Liver, systemic	Organ dysfunction, pulmonary hemorrhage ^e
European brown hare syndrome virus	Lagovirus	Hare	Liver, systemic	Organ dysfunction, pulmonary hemorrhage
Bovine enteric calicivirus (Newbury-1 virus)	Nebovirus	Cattle	Enteric	Gastroenteritis
Bovine enteric calicivirus (Nebraska virus)	Nebovirus	Cattle	Enteric	Gastroenteritis
Feline calicivirus	Vesivirus	Cat	Mouth, upper respiratory	Stomatitis, pneumonia
Feline calicivirus-VS	Vesivirus	Cat	Systemic	Fulminant organ dysfunction ^f
San Miguel sea lion virus	Vesivirus	Sea lion	Mucosal, systemic	Skin (flipper) lesions, pneumonia
Canine calicivirus (No. 48)	Vesivirus	Dog	Enteric	Gastroenteritis
Vesivirus isolate 2117	Vesivirus	Unknown	Unknown	Unknown ^g
Tulane virus	Unclassified	Monkey	Enteric	Gastroenteritis
St. Valérian virus (AB90)	Unclassified	Pig	Enteric	Not established
Bayern virus	Unclassified	Chicken	Enteric	Not established

^aSite of replication is based on observed pathologic effects in tissue and in some cases, confirmed by immunohistochemistry. For many caliciviruses, the primary site of replication in the host has not been fully established.

^bThe characteristic clinical disease associated with each representative calicivirus strain is shown. Swine norovirus,⁴⁴⁸ St. Valérian virus,²⁵¹ and Bayern virus⁵⁰⁹ were detected in screening surveys of nonselected stool specimens: the clinical disease outcome has not been established. Norwalk virus, representative of the human noroviruses associated with acute gastroenteritis, is generally associated with self-limiting vomiting and diarrhea of 24 to 48 hours' duration. However, the illness can be severe and life-threatening in certain individuals (see text). Sapporo virus, representative of the human sapoviruses associated with acute gastroenteritis, has most often been associated with self-limiting gastroenteritis in younger age groups.⁸⁹ In general, infection outcome in the family *Caliciviridae* can range from asymptomatic (subclinical) to lethal.

^cMost variants of the MNV-1 strain of murine norovirus are lethal only in certain mice that lack an innate immune system, but evidence exists for varying pathogenicity among MNV strains and variants.^{26,217,467,507}

^dFirst case report described illness in one lion cub,³⁰⁴ natural history not established.

^eRabbit hemorrhagic disease virus emerged as a highly lethal disease in rabbits in China in 1984,²⁹⁰ but was likely endemic in rabbits worldwide prior to 1984.²²⁴

^fFeline calicivirus strains have emerged in recent years designated as "virulent systemic" (VS) that are associated with high morbidity and mortality in cats. In addition, the virus can cause a persistent, asymptomatic infection in cats.³⁸⁵

^gVesivirus 2117 was discovered as a contaminant in cultured Chinese hamster ovary cells.³⁵⁷

mild to life-threatening, and evidence exists for the emergence of calicivirus strains with increased virulence. Asymptomatic infection occurs in susceptible populations,^{106,377} and shedding of virus can extend days to weeks after resolution of acute symptoms.^{24,140}

Adult volunteer studies have been successful in defining important features of norovirus gastroenteritis, pathogenesis, and immunity.²¹³ Presently, there is no animal model that directly recapitulates the full range of disease symptoms observed in humans (see Clinical Features), but animals in which evidence for infection has been reported following challenge with human noroviruses include gnotobiotic piglets⁸⁴ and calves,⁴⁴⁰ monkeys,^{394,447} and chimpanzees.^{48,158,512}

Noroviruses have been detected in the feces of mice (e.g., strain MNV-1),^{210,217,337} pigs (strain SW418),⁴⁴⁸ cattle (strain Jena virus),²⁷⁵ and dogs (strain 170/07),³⁰⁵ leading to the investigation of these viruses as model systems for the human

noroviruses. Bovine norovirus (strain Jena) caused diarrhea and severe blunting of the small intestinal villi in newborn calves similar to that observed in human norovirus infection, and virus antigen-positive cells were observed in epithelial cells of the villi and the lamina propria.³⁶⁴

Entry into the Host

Noroviruses enter the body predominantly via the oral route. Virions are acid stable, consistent with an ability to survive passage through the stomach. Indirect evidence from epidemiologic studies suggests that viruses can enter also via aerosols, such as in those generated from the explosive vomiting that often occurs during illness.^{66,70,302,303,372}

Based on volunteer studies with NV, the incubation period is short, ranging from 10 to 51 hours, with a mean of 24 hours.^{24,43,112,113,442,511} Acute illness usually lasts about 24 to 48 hours. The incubation period recorded in 22 naturally

occurring outbreaks of norovirus gastroenteritis was between 24 and 48 hours in 20 of the outbreaks, and the range was from 4 to 77 hours.²¹⁶ The incubation period of experimentally induced Snow Mountain virus illness ranged from 19 to 41 hours, with a mean of 27 hours.¹¹⁶

Studies in volunteers demonstrated that the Norwalk, Hawaii, Montgomery County, and Snow Mountain viruses induced gastroenteritis when administered by the oral route.^{112,113,206,265,332,442,511} Transmission via the respiratory route has not been established for this group of agents, although it has been suggested from epidemiologic observations in selected settings.^{66,71,302,408} The virus was detected in vomitus obtained from infected volunteers¹⁵⁷; vomitus has been considered to be a source of transmission in certain settings.⁷⁰ Oral-to-oral transmission has been suggested: norovirus RNA was detected in washings from the mouths of individuals with norovirus infection (in one case, up to 2 weeks postillness) and in 10/17 (59%) of patients hospitalized with norovirus gastroenteritis who had vomited within 24 hours prior to sample collection.²³¹ Nasopharyngeal washings from a volunteer with experimentally induced Norwalk gastroenteritis did not induce illness in three volunteers.¹¹²

Site of Primary Replication

The site of primary replication for the noroviruses has not been established, but it is assumed that they replicate in the upper intestinal tract. Biopsies of the jejunum of volunteers who develop gastrointestinal illness following oral administra-

tion of the Norwalk or Hawaii virus exhibit histopathologic lesions.^{3,114,413,414} A broadening and blunting of the villi of the proximal small intestine occurs, although the mucosa itself remains histologically intact (Fig. 20.8). Infiltration with mononuclear cells and cytoplasmic vacuolization is also observed. Biopsies obtained during the convalescent phase of illness are normal. Blunting and atrophy of the villi was observed also in the small intestine of pigs infected with porcine enteric calicivirus (PEC), a sapovirus,¹³² and in newborn calves infected with Jena virus, a bovine norovirus.³⁶⁴ When viewed by transmission EM, the epithelial cells are intact, but there is shortening of the microvilli. Virus has not been observed in epithelial cells of the mucosa by EM. Of interest is that the characteristic jejunal lesion has also been observed in volunteers who were fed NV or Hawaii virus but who did not become ill.^{320,413,414} Histologic lesions are not observed in the gastric fundus, antrum, or rectal mucosa of volunteers with NV-induced illness.⁵⁰² The examination of intestinal biopsies from pediatric patients infected with norovirus who had undergone small intestinal transplantation showed increased mononuclear infiltrates in the lamina propria and villous blunting when compared with uninfected controls.³³⁴ Duodenal biopsies from immunocompetent individuals with acute norovirus gastroenteritis showed evidence of shortened villus height (which decreased the overall villus surface area by approximately 47%) and noted also the infiltration of a dense population of intraepithelial CD8 lymphocytes.⁴⁷²

A transient malabsorption of fat, d-xylose, and lactose is observed during experimentally induced NV illness.^{43,413} Levels

FIGURE 20.8. Pathology of norovirus and sapovirus infection in the jejunum. **A:** Normal-appearing jejunal tissue from biopsy of a volunteer prior to challenge with Norwalk virus (NV). Hematoxylin and eosin (H&E), 390. **B:** Broadened and flattened villi in jejunal biopsy tissue from same volunteer during illness with Norwalk-induced gastroenteritis. H&E, 390. **C:** Scanning electron microscopy (EM) showing normal-appearing jejunal tissue from biopsy of pig prior to challenge with porcine enteric calicivirus. **D:** Scanning EM showing shortening, blunting, fusion, or absence of villi in jejunal biopsy from same pig following challenge with porcine enteric calicivirus. (**A,B** from Agus SG, Dolin R, Wyatt RG, et al. Acute infectious nonbacterial gastroenteritis: intestinal histopathology. Histologic and enzymatic alterations during illness produced by the Norwalk agent in man. *Ann Intern Med* 1973;79:18–25, with permission. **C,D** from Flynn WT, Saif LJ, Moorhead PD. Pathogenesis of porcine enteric calicivirus-like virus in four-day-old gnotobiotic pigs. *Am J Vet Res* 1988;49:819–825, with permission.)

of small intestinal brush-border enzymes (trehalase and alkaline phosphatase) were significantly decreased when compared with baseline and convalescent-phase values, whereas adenylate cyclase activity in the jejunum was not elevated following NV- or Hawaii virus—induced illness.^{3,265} Gastric secretion of hydrochloric acid, pepsin, and intrinsic factor did not appear to be altered during NV illness.³²⁰ Elevation of serum transaminase levels was reported in four pediatric patients at approximately two weeks following acute illness.⁴⁷⁴

A marked delay in gastric emptying was observed in infected volunteers who became ill and developed the typical jejunal mucosal lesion.³²⁰ It has been proposed that abnormal gastric motor function is responsible for the nausea and vomiting associated with these viral agents.³²⁰ An analysis of epithelial barrier and secretion function in norovirus-positive human duodenal biopsy tissue showed that the tight junction proteins occludin, claudin-4, and claudin-5 were reduced, and anion secretion was stimulated.⁴⁷² It was proposed that norovirus diarrhea could result from both epithelial barrier and secretory pathway dysfunction.

Spread in the Host

The major site of norovirus replication is presumably the upper small intestinal tract (duodenum and upper jejunum), but there is evidence that extraintestinal spread of the virus can occur. Viral RNA has been detected in serum and cerebrospinal fluid of a 23-month-old patient with encephalopathy.¹⁹⁶ In an analysis of 39 patients with acute norovirus gastroenteritis (confirmed by the detection of viral RNA in stool), norovirus RNA was detected in the serum of 6 (15%) patients by real-time PCR.⁴⁵³ Human noroviruses can establish an enteric infection in gnotobiotic piglets⁸⁴ and chimpanzees⁴⁸ when administered by the intravenous route.

Cell and Tissue Tropism

Human noroviruses are presumed to target cells in the small intestine due to the observed pathologic lesion (blunted villi), but the specificity of this interaction has been difficult to establish. Radiolabeled Norwalk rVLPs bind to a variety of cultured cell types, and in certain cells, they are apparently internalized with a low efficiency.⁴⁹⁷ Norwalk VLPs bind to the surface of human intestinal epithelial cells bearing H1 or H2/3 HBGAs present in fixed tissue sections from secretor-positive (but not secretor-negative) individuals,³⁰¹ but the expression of these antigens on the surface of Huh-7 cells (a human liver cell line) does not confer full susceptibility to a productive Norwalk virus infection.¹⁶² It was speculated that human noroviruses might bind nonepithelial cells in the gut: Sakai virus (a GII norovirus) was shown to bind to cells within the lamina propria and Brunner gland of human duodenum,⁷³ and chimpanzees infected with Norwalk virus displayed Norwalk virus antigen-positive cells within the lamina propria of the upper small intestine.⁴⁸ The murine norovirus infects macrophage and dendritic cells of the mouse immune system,⁵⁰⁷ but this cell tropism has not been confirmed for human noroviruses in *in vitro* studies.²⁵⁷ Gnotobiotic piglets challenged with a GII.4 norovirus strain displayed virus-positive enterocytes in the duodenum and jejunum.⁸⁴

For years speculation was that a genetically determined variation in virus receptors in the intestinal tract might be responsible for long-term resistance to NV.^{30,41,98,239,369} Recent studies

have found evidence for such a mechanism that involves the ABH and Lewis carbohydrate antigens present on gut epithelial cells,³⁰¹ which is reviewed elsewhere.^{117,191,261,262,461} Expression of these carbohydrate antigens on cells is controlled by enzymes that are products of alleles at the ABO, FUT2, and FUT3 loci. Individuals with two mutated FUT2 alleles, and therefore devoid of H-type antigens on their gut (and other mucosal) epithelial cells, are called *nonsecretors*. It was first observed that RHDV (lagovirus) virions and RHDV rVLPs were able to bind to ABH histo-blood group antigens (present also on human blood cells) that were expressed on epithelial cells of the respiratory and digestive tracts of rabbits.⁴⁰³ Furthermore, the binding of RHDV to human blood cells was blocked by saliva from human individuals who were secretor positive for H carbohydrates, but not from individuals who were nonsecretors. The subsequent discovery that Norwalk VLPs could bind to HBGAs expressed on human intestinal epithelial cells³⁰¹ suggested that genetically determined host factors relating to histo-blood group antigens might play a role in mediating susceptibility to infection. This hypothesis was confirmed in human volunteers, in which the secretor status of the individual was a major correlate in susceptibility to infection with NV.²⁶⁹ On oral challenge with NV, only secretor individuals with H type 1 antigens were susceptible to infection, whereas nonsecretors were resistant. In a retrospective analysis of volunteers in earlier NV challenge studies, the secretor status was again identified as a major correlate of susceptibility to infection.¹⁹⁰ Furthermore, the ABO blood group antigens have also been linked to susceptibility to Norwalk infection, with B blood group antigen individuals rarely showing evidence of infection and illness with NV.^{192,269} Variation likely exists among the noroviruses in their recognition of host cell carbohydrates.^{61,91,186,461} Infection in volunteers challenged with GII Snow Mountain virus (unlike those challenged with NV) showed no correlation between ABH secretor status and susceptibility,²⁶⁸ suggesting that the link to protection in type B individuals might be limited to GI noroviruses.³⁹⁵ Attempts to correlate susceptibility with ABH secretor status or blood type in naturally occurring disease have yielded variable results.^{170,255,351,441}

The role of HBGA recognition by noroviruses has been the subject of intense study from the perspective of structure,²⁴² evolution,^{47,105,272} and host restriction.^{63,262} It is not yet clear whether these molecules serve only as attachment ligands on host cells or are functional receptors that enable the entry of virus (see Mechanism of Attachment).

Immune Response

Immunity to noroviruses in humans is poorly understood.³¹⁰ Adults consistently demonstrate a high degree of susceptibility to both naturally occurring and experimentally induced NV illness. In some norovirus outbreaks, more than 80% of adults became ill.²¹⁶ In addition, approximately 50% of unselected adult volunteers consistently developed illness following challenge with NV.^{43,112,442,511} Resistance to norovirus illness likely involves a complex interplay between the genetic and immunological susceptibility of the host and exposure to evolving norovirus strains.

Adaptive Immunity

Because serum or intestinal secretory neutralizing antibodies to the noroviruses cannot yet be measured in tissue culture, most

of the information about immunity comes from early volunteer studies. Although the use of high doses of challenge virus in these early studies has been noted,¹⁴⁷ they established that there are two forms of immunity to NV: one is short term and the other is long term.^{112,369,511} Short-term immunity, which follows the traditional pattern, is apparently virus (possibly serotype) specific. Thus, volunteers who become ill following NV (GI.1) challenge are usually resistant to rechallenge with this virus 6 to 14 weeks later. Challenge of such volunteers with the heterotypic Hawaii virus (GII.1), however, induces illness. Similarly, volunteers who recently became ill following infection with Hawaii virus are susceptible to challenge with NV.⁵¹¹ Long-term immunity, however, deviates from the traditional pattern. Twelve volunteers who were challenged with the NV on two occasions, 27 to 42 months apart, exhibited two different patterns of resistance to sequential challenge.³⁶⁹ Six volunteers developed gastrointestinal illness following the initial challenge, and they developed it again following rechallenge 27 to 42 months later. In contrast, the other six individuals failed to become ill following the initial challenge and were also resistant after rechallenge 31 to 34 months later. Serologic studies in which prechallenge serum antibodies to NV were measured by IEM and radioimmunoassay (RIA) failed to provide an explanation for the difference in susceptibility.^{99,156,369} Paradoxically, volunteers who did not become ill had little, if any, antibody to NV measurable by IEM in either prechallenge serum specimen.³⁶⁹ Also, they failed to develop a significant serologic response following each challenge. Volunteers who became ill following each challenge, and who were evaluated serologically, developed a serologic response after each challenge, however. The observation that serum antibody to NV does not correlate with resistance to illness has been reproduced in more recent volunteer studies.^{149,206,269} It was found also that the levels of local jejunal antibodies did not correlate with resistance to illness in volunteer studies and during natural outbreaks of disease.^{30,42,156,205,206,297} Naturally acquired immunity, however, may play some role in protection at the mucosal level. A recent volunteer study showed that the development of a rapid mucosal IgA response (indicating prior exposure to NV or a related norovirus) was associated with resistance to illness following challenge with NV.²⁶⁹ Furthermore, antibody was shown to be critical for the clearance of MNV in the mouse model.⁶⁸

The discovery that NV and other human noroviruses recognize HBGAs has led to the development of assays that measured HBGA carbohydrate-blocking activity (or "blockade") of serum antibodies.²⁷⁹ The presence of antibodies that blocked binding of Norwalk VLPs to H type 1 or H type 3 glycans at the time of Norwalk virus challenge was shown to correlate with protection from illness in adult volunteers, leading to the proposal that HBGA blocking assays might serve as a surrogate test for neutralization in the absence of traditional cell culture-based virus neutralization assays.³⁸⁷ Consistent with this, chimpanzees vaccinated with a Norwalk VLP immunogen and resistant to Norwalk virus infection when subsequently challenged were shown also to develop serum antibodies that block binding of Norwalk VLPs to synthetic HBGA carbohydrates.⁴⁸ Application of this technique in the first efficacy study of norovirus vaccines in adult volunteers showed a correlation between levels of prechallenge HBGA-blocking titers and protection from illness.²² A hemagglutination inhibition assay (HAI) to

measure serum antibodies was shown also to correlate with protection from illness in volunteers challenged with Norwalk virus.^{101,193}

Cell-Mediated Immunity

Cell-mediated immune responses were studied in volunteers following oral immunization with Norwalk rVLPs.⁴⁵² The VLPs elicited a cell-mediated immune response that included virus-specific proliferative responses. There was an increase in γ -interferon (IFN) in the absence of IL-4 production, suggesting a dominant T-helper type 1 (Th-1) pattern of cytokine production. In a study of 15 volunteers infected with Snow Mountain virus, significant increases in serum γ -IFN and IL-2, but not IL-6 or IL-10, were detected on day 2 after challenge, again showing a dominant Th-1 response.²⁶⁸ Depletion of CD4+ cells prior to stimulation of peripheral blood mononuclear cells with norovirus antigen led to a decrease in γ -IFN, again consistent with a Th-1 dominant response that is characteristic of cell-mediated immunity.²⁶⁸

Both CD4 and CD8 T cells are required for virus clearance from the intestine following challenge with MNV.⁶⁷ Evidence for cross-reactive T-cell epitopes shared among different norovirus genogroups and genotypes was found in mice immunized with VLPs representing human and murine noroviruses.²⁸⁰

Innate Immunity

The innate immune response was found to be important in the control of murine norovirus (strain MNV-1) in mice: certain mouse strains deficient in components of the innate immune system (such as STAT1 or receptors for interferon) developed a disseminated, lethal infection when challenged with MNV-1.²¹⁷ It has been reported that MDA-5, an intracellular sensor of double-stranded RNA, may be involved in the recognition and control of MNV.³¹⁵ Caliciviruses have been shown to be sensitive to various types of interferon *in vitro*.^{76,78,79,80,229,328}

Release from Host and Transmission

Noroviruses are released from the enteric tract of the host in feces and have been detected also in vomitus.^{151,157,227,317} Viral RNA can be detected in feces before the onset of symptoms and shedding in stool can last several days to weeks in immunocompetent individuals^{24,141,149,360} and even longer in immunocompromised patients.^{136,222,223,289,406,450} In a study of 13 elderly patients (60 to 98 years of age), the average duration of norovirus shedding was 14.3 days, with some individuals shedding up to 32 days.¹⁶ In pediatric patients (3 months to 7 years of age), the average length of shedding was 16 days, with three patients younger than 6 months of age shedding for more than 40 days.³³⁸ Studies of the natural history of norovirus in a community found that 26% of 99 patients examined shed virus (detected by reverse transcriptase [RT]-PCR) up to 3 weeks after the onset of illness, with the highest rate (38%) of prolonged shedding in children younger than 1 year of age.³⁹³ This observation indicates that infected individuals recovering from norovirus illness can continue shedding beyond the symptomatic period, a finding that has implications in the management of outbreaks.^{100,329,367,388,477,496} Norovirus RNA has been detected in washings from the mouths of individuals who experienced norovirus infection for several days after symptoms subsided, suggesting that oral-to-oral transmission of norovirus might occur.²³¹ The detection of norovirus RNA

in the sera of children with gastroenteritis has been reported, but it is not known whether this RNA corresponds to that of circulating infectious virus (viremia) or noninfectious (inactivated) virus present in circulating immune cells.⁴⁵³

Noroviruses are spread by several modes of transmission (see Fig. 20.9B for a summary of the reported modes of transmission in 5,036 norovirus outbreaks that occurred in Europe

between 2000 and 2011). The predominant modes of transmission for the noroviruses are person-to-person contact and food- or water-borne spread.²⁴⁸ Contamination of surfaces and objects by infected individuals can lead to inadvertent exposure.^{184,283,477} Several epidemiologic investigations have linked exposure to noroviruses in air or in aerosolized vomitus with infection.^{31,66,142,302,303,408}

FIGURE 20.9. Features of norovirus epidemiology. **A:** Settings of transmission for 233 outbreaks of nonbacterial gastroenteritis in the United States from July 1997 to June 2000. Noroviruses were detected in stool samples from individuals in 93% of these outbreaks by reverse transcriptase-polymerase chain reaction (RT-PCR). (Data adapted from Fankhauser RL, Monroe SS, Noel JS, et al. Epidemiologic and molecular trends of “Norwalk-like viruses” associated with outbreaks of gastroenteritis in the United States. *J Infect Dis* 2002;186:1–7; and <http://www.cdc.gov/ncidod/dvrd/revb/gastro/norovirus.htm>.) **B:** Reported modes of transmission for 5,036 norovirus outbreaks that occurred over a 5-year period (2001–2006) in Europe. (Data adapted from Kroneman A, Verhoef L, Harris J, et al. Analysis of integrated virological and epidemiological reports of norovirus outbreaks collected within the Foodborne Viruses in Europe network from 1 July 2001 to 30 June 2006. *J Clin Microbiol* 2008;46:2959–2965; and www.rivm.nl/en/aboutrivm/projects/index.) **C:** Norovirus genotypes associated with gastroenteritis outbreaks that occurred over an 11-year period (2000–2011) in Europe. The Genogroup II noroviruses were detected in 2,256 (90%) of the 2,512 samples analyzed, with the GII.4 genotype detected in 1,627 (65%) of the total number tested. (Data from the Foodborne Viruses in Europe Network, <http://www.noronet.nl>. Personal communication, A. Kroneman and M. Koopmans.)

The explosive nature of some NV outbreaks, in which a large number of persons become ill within 24 to 48 hours, indicates that infection is often acquired from a common source. This was suggested in the original NV outbreak, but a common-source exposure could not be identified.² Later, a review of 38 NV-associated outbreaks suggested that a common source of infection was likely in 31 (82%).²¹⁵ The vehicle of transmission could be identified in 17 of the 31 outbreaks, including water in 13 instances and food in four others. Water-borne infection was attributed to a municipal water system (twice), semipublic water supply (seven times), stored water on a cruise ship (twice), and recreational swimming (twice). The food-borne outbreaks were associated with the ingestion of oysters or salad. Primary person-to-person transmission occurred in 7 of the 38 outbreaks.²¹⁶ Sufficient data were available from 26 of the outbreaks to permit estimation of secondary attack rates.²¹⁶ In 20 of 23 common-source outbreaks and in each of 3 person-to-person outbreaks, secondary transmission was observed, with attack rates ranging from 4% to 32%. In a large outbreak for which age data were available, the secondary attack rate was highest in children younger than 10 years of age. The median duration of the 38 outbreaks was 7 days (ranging from 1 day to 3 months). The number of individuals who became ill ranged from 2 to 2,000, with the attack rate being higher in common-source outbreaks (median 60%, range 23% to 93%) than in primary person-to-person outbreaks (median 39%, range 31% to 42%).²¹⁶ In the Colorado outbreak caused by the Snow Mountain virus, 61% of the 418 illnesses began on a single day.^{116,332} A water-borne source was suggested as the etiologic agent because the attack rate was directly related to the amount of water- or ice-containing beverages consumed. In addition, the water supply was contaminated by a leaking septic tank and was inadequately chlorinated. The efficient transmission of human caliciviruses by contaminated food and water vehicles has raised concerns about public safety in a global market economy.^{147,379,411,482,491}

The infectious dose for noroviruses is low, with an estimated median infectious dose of 18 viruses.⁴⁶⁶ Exposure to higher levels of virus likely increases the risk of illness.²⁸⁸ In a study that examined norovirus fecal load, higher numbers (greater than 100-fold) of norovirus genome copies were detected in individuals shedding GII (median, 3.0×10^8 genome copies per gram feces) strains compared to GI (median, 8.4×10^5 genome copies per gram feces).⁷⁵ It was proposed that the higher levels of GII shedding might account for a higher transmissibility of these viruses through the fecal–oral route.⁷⁵ However, high levels of GI shedding have been reported: the median peak of GI Norwalk virus shed in the stool of 16 volunteers was 9.5×10^{10} genome copies per gram feces.²⁴

Noroviruses are remarkably stable. The NV retains infectivity for volunteers following (a) exposure of the stool filtrate to pH 2.7 for 3 hours at room temperature, (b) treatment with 20% ether at 4°C for 18 hours, or (c) incubation at 60°C for 30 minutes.¹¹² Norwalk virions remain infectious when stored in ground water at room temperature in the dark for as long as 61 days, and RNA could be detected in such samples after storage at room temperature for 3 years.⁴²⁰ NV is resistant to inactivation following treatment with 3.75 to 6.25 mg/L of chlorine (free residual chlorine of 0.5 to 1.0 mg/L), a chlorine concentration consistent with that found in a drinking water distribution system.²²⁵ NV, however, is inactivated following

treatment with 10 mg/L of chlorine, a concentration that is used to treat water supply systems after contamination has been detected. NV is more resistant to inactivation by chlorine than poliovirus type 1, human rotavirus (Wa), simian rotavirus (SA11), or f2 bacteriophage.²²⁵

Virulence

Virulence determinants have not been defined for the human noroviruses, but differences in clinical outcome, ranging from asymptomatic infection to life-threatening diarrhea, suggest that strain differences exist,¹⁸⁷ as shown for other caliciviruses (Table 20.3). A compelling feature of norovirus epidemiology that supports strain differences (especially in the GII.4 genotype) is the striking variation in disease prevalence in certain years, with sharp increases in global outbreaks and disease burden.^{123,147}

Persistence

Noroviruses have been associated with prolonged infection in immunocompromised patients,^{139,223,348,396} and, therefore, nosocomial transmission of noroviruses to such patients should be prevented by precautionary measures.⁴³⁰ Nine adult patients receiving kidney allografts and undergoing immunosuppression were shown to shed norovirus for periods ranging from 97 to 898 days.⁴¹² One study documented chronic diarrhea in a heart transplant patient undergoing immunosuppressive therapy who shed a GII norovirus strain over 2 years.³⁴⁸ A 36-yr year-old patient with human immunodeficiency virus (HIV) infection and admitted to the hospital for chronic diarrhea was reported to shed norovirus for 15 months (with stools collected 5 months prior to hospitalization identified as norovirus-positive).⁵⁰⁴ Deaths in two chronic lymphocytic leukemia (CLL) patients were associated with prolonged norovirus diarrhea.⁶² Immunocompromised patients with norovirus infection were reported to be at increased risk for the development of pneumonia intestinalis.²²⁸

EPIDEMIOLOGY

Age

Noroviruses have been associated with infection and disease in all age groups. The estimated overall prevalence of norovirus in infants and young children hospitalized for the treatment of gastroenteritis is approximately 12% according to a recent review of published studies.³⁷¹ making the noroviruses second only to the rotaviruses as etiologic agents of severe gastroenteritis in this young age group. In the surveillance period following efficacious rotavirus vaccination in Finnish infants, noroviruses became the single most important cause of acute gastroenteritis.⁵¹⁹

The noroviruses have frequently been associated with gastroenteritis in the elderly, especially those living in institutional settings such as nursing homes.^{126,153} An estimated 25% of 233 nonbacterial gastroenteritis outbreaks reported to the Centers for Disease Control and Prevention (CDC) from July 1997 to June 2000 occurred in the hospital or nursing home setting.¹²⁶

Morbidity/Mortality

Although precise data on morbidity and mortality are not available, several studies estimate a significant burden from norovirus-associated disease.^{169,409} In the United States, an estimated 71,000 hospitalizations are associated with norovirus

gastroenteritis each year, at a cost of \$493 million per year.²⁸⁶ In a review of published studies, noroviruses were consistently reported as the second most important cause (after rotavirus) of severe gastroenteritis in infants and young children worldwide, with an estimated 200,000 deaths per year in children younger than 5 years of age in developing countries.³⁷¹ Noroviruses have been linked to gastrointestinal illness in neonates.³²¹ Norovirus infection and disease in preterm infants receiving intensive care in a hospital nursery unit have been reported,¹⁹ and in one such setting necrotizing enterocolitis occurred more frequently in preterm infants with norovirus infection.⁴⁴⁵ In an analysis of medical registrations (such as doctor visits, hospitalizations, and deaths) associated with gastroenteritis of unspecified cause during periods of high norovirus outbreak activity in the Netherlands, it was estimated that elderly individuals (65 years of age and older) were at increased risk for serious illness requiring medical intervention and death.⁴⁷⁸ In Sweden, an overall excess mortality rate was found in elderly patients hospitalized for the treatment of severe norovirus gastroenteritis that was acquired in the community,¹⁶⁴ and a case-fatality rate of 2% was reported in a large norovirus outbreak that occurred in six nursing homes in Israel.⁶⁰ An analysis of the role of various enteric pathogens in hospitalized patients in Canada (from 2001 to 2004) estimated that noroviruses were responsible for a mean hospitalization incidence rate of 1.6 cases per 100,000 and that the average age of hospitalized patients was 59 years old.⁴⁰⁴ Over the 4-year period, 43 deaths were attributed to noroviruses, making it a leading cause of mortality among the enteric pathogens studied.⁴⁰⁴ Noroviruses have been associated with increased morbidity and mortality in patients with an underlying illness such as cardiovascular disease or who are immunosuppressed or receiving chemotherapy.^{62,216,223,232,312,400,417,430}

Origin and Spread of Epidemics

Noroviruses are the single most important cause of nonbacterial gastroenteritis outbreaks. In an analysis of 233 nonbacterial gastroenteritis outbreaks reported to the CDC between July 1997 and June 2000, 217 (93%) were associated with noroviruses.¹²⁶ In a larger survey of 3,714 nonbacterial gastroenteritis outbreaks that occurred in Europe between 1995 and 2000, 85% were associated with noroviruses.²⁸⁷ Outbreaks often occur in hospitals, long-term care facilities, camps, recreational areas, elementary schools, daycare centers, cruise ships, retirement centers, colleges, restaurants, social events with catered meals, families, the military, prisons, and community settings (see Fig. 20.9A for predominant settings of outbreaks in the United States between 1997 and 2000). Outbreaks can vary in size, involving small family groups to hundreds of individuals.^{195,311,513}

Especially noteworthy is the predominant role of the noroviruses in food-related outbreaks of gastroenteritis. Noroviruses are the leading cause of food-borne illness in the United States (followed by *Salmonella* [nontyphoidal], *Clostridium perfringens*, *Campylobacter* spp., and *Staphylococcus aureus*), accounting for approximately 26% of all reported outbreaks.⁴⁰⁹ An analysis of 8,271 food-borne outbreaks reported to the CDC (1991–2000) showed that norovirus outbreaks were often larger than bacterial outbreaks (median persons affected: 25 vs. 15), with 10% of the affected individuals seeking medical care and 1% being hospitalized.⁵⁰¹ In a study of water-borne outbreaks in Finland, 18 (64%) of 28 outbreaks evaluated were

associated with norovirus.³¹³ Bivalve mollusks (such as oysters and mussels) are an important cause of food-borne norovirus outbreaks.^{9,234,285,316,335,495}

Noroviruses have also been documented as important agents of gastroenteritis in military populations in several different areas of the world.^{4,20,104,314} Among U.S. military personnel deployed to South America or West Africa, NV infection was detected in 10% of ill personnel, second in importance to enterotoxigenic *Escherichia coli*, which was the most frequently encountered pathogen (17%).⁵² In addition, large-scale outbreaks of gastroenteritis have been attributed to the noroviruses on ships such as aircraft carriers on which hundreds of crew members became ill.^{45,94,365,423}

Although the majority of traveler's diarrhea has been attributed to enterotoxigenic *E. coli*,⁴⁰ an increasing number of reports have linked noroviruses to such illness.^{5,6,17,81,121,405} Norovirus transmission during airplane travel, in addition to that on recreational cruise ships, has been reported, illustrating the potential ease with which strains can be spread globally.^{233,469,481,500}

Prevalence and Seroepidemiology

Noroviruses have a worldwide distribution. Most individuals in both developed and developing countries show evidence of infection with norovirus before adulthood, reflecting the global distribution and endemic nature of these viruses.²⁰³ A study of Finnish infants and children, aged 0 to 14 years, found that antibody prevalence against GII.4 noroviruses reached 91.2% in children older than 5 years of age.³⁵³ The prevalence of antibody to the GII viruses (Mexico, Hawaii, or Lordsdale) appears to be greater than that of the GI viruses in most^{97,204,355,431} but not all^{102,109} studies, which likely reflects the predominance of circulating GII strains. The prevalence of norovirus antibodies characteristically increased more gradually by age in developed than in developing countries.²⁰³

The incidence of norovirus gastroenteritis has been estimated in several community-based studies. In the United States, an enhanced surveillance study of acute gastroenteritis (that included pathogen identification with diagnostic assays) in a single state (Georgia) estimated that norovirus was the predominant cause of acute gastroenteritis, accounting for 6,500 (16%) and 640 (12%) per 100,000 person-years of community and outpatient acute gastroenteritis episodes, respectively.¹⁶⁹ In the Netherlands, 18% of the community cases of gastroenteritis over a single winter season and at least 5% of gastroenteritis cases that resulted in a visit to a physician were associated with norovirus infection.²⁴¹ Furthermore, a 1-year prospective population-based cohort study showed that noroviruses were the single most important cause of gastroenteritis overall in nearly all age groups in the Netherlands.¹⁰⁶ In Germany, the incidence of norovirus gastroenteritis in the community requiring medical attention was reported as 626 cases/per 100,000 person-years, making it the predominant known cause of acute gastroenteritis in that country.²¹⁸ In England, the community incidence of norovirus gastroenteritis was 4.5 cases/per 100 person-years, corresponding to approximately 2 million episodes per/year.³⁷⁶

Genetic Diversity of Virus

Molecular epidemiologic studies have demonstrated a marked genetic diversity among circulating noroviruses. Genetic typing

of circulating strains has proven to be a useful tool in elucidating the source and spread of outbreaks,^{247,482,483} and regional data-sharing networks have been established in several areas of the world.^{133,246,336,480} Genetic typing systems for the noroviruses have been proposed based on relatedness in the complete VP1 capsid protein, which presumably would correlate with the antigenic specificity.^{247,520} One such system (Table 20.4) shows the division of the genus *Norovirus* into

six major phylogenetic clades, or genogroups, designated GI through GV. Genogroups I, II, and III are further subdivided into 9, 21, and 3 genotypes, respectively.

Large-scale molecular epidemiologic studies have given insight into important genetic features of the noroviruses. An analysis of the genetic typing data from 2,512 noroviruses associated with outbreaks in Europe from 2000 to 2011 shows the marked genetic variation in the genotypes of circulating

strains (Fig. 20.9C). The GII noroviruses, particularly those of the GII.4 cluster, were the predominant viruses detected, and this distribution reflects the epidemiologic pattern observed in most other parts of the world. In an analysis of 773 norovirus outbreaks reported to the CDC from 1994 to 2006, 629 (81.4%) were caused by GII viruses and 342 (44.2%) of these were caused by GII.4 strains.⁵²¹ Major shifts in the predominant circulating strain can occur,^{56,127,138,284,350,389,485,499,521} and the factors (host or viral) responsible for the emergence of an epidemic norovirus strain are under investigation. Sequence analysis of the GII.4 noroviruses that emerged on a global level in the early 2000s identified the presence of an amino acid insertion in the VP1 P2 domain, suggesting a possible change in the antigenic or receptor recognition phenotype.¹¹⁰ Further evolution in the GII.4 cluster was described,⁵⁶ and several studies have examined the possibly unique propensity of this genotype to undergo genetic (and antigenic) drift.^{10,47,51,57,118,271,272,336,421,428} Genetic variation has been detected in other regions of the genome such as the emergence of the “GGIIB-pol” polymerase type that was found in norovirus strains in combination with several different VP1 genotypes.^{389,390} Additional reports of unique polymerase sequences have led to the conclusion that recombination is a driving mechanism of norovirus evolution.^{55,144}

Evidence for mixed norovirus infections within the same individual or within the same outbreak has been reported in many epidemiologic studies.^{14,54,150,167,282,449} In addition, a marked genetic diversity among norovirus strains has been documented in pediatric patients.^{137,173,235,307,522} Such diverse and mixed infections may allow recombination between RNA genomes, a possibility suggested from sequence analyses of naturally occurring noroviruses in several species.^{55,124,171,177,198,362,398,488} The presence of diverse norovirus sequences in shellfish samples is common,^{87,95,260} suggesting another potential source for mixed infection. Infection of feline kidney cells with two distinct recombinant FCV strains bearing different fluorescent markers has demonstrated that co-infection of the same cell can readily occur, further supporting the potential for recombination of RNA genomes during replication.¹

CLINICAL FEATURES

Viral gastroenteritis is generally considered to be mild and self-limiting, although the illness can be incapacitating during the symptomatic phase that usually lasts 24 to 48 hours (Fig. 20.10). Illness induced by the noroviruses can be sufficiently severe to require medical intervention, with an increased risk for life-threatening dehydration at both ends of the age spectrum.^{20,104,216,232,366,400,423} Immunocompromised patients with norovirus infection are at increased risk for morbidity and mortality, and an increasing number of reports have linked norovirus to chronic gastroenteritis in patients undergoing transplantation or chemotherapy.^{46,131,312,401,406,417,430,450,494} (see Treatment).

Clinical manifestations observed in 31 volunteers experimentally infected with noroviruses who became ill included the following: fever above 99.4°F (45%), diarrhea (81%), vomiting (65%), abdominal discomfort (68%), anorexia (90%), headache (81%), and myalgias (58%).⁵¹¹ The illnesses were characteristically mild and usually lasted 24 to 48 hours; however, one volunteer was given parenteral fluid because he

FIGURE 20.10. Clinical course of norovirus disease.

vomited 20 times within a 24-hour period. The number of clinical signs and symptoms can vary among volunteers receiving the same inoculum.¹¹³ Illnesses induced by the Hawaii, Montgomery County, and Snow Mountain viruses in volunteers cannot be distinguished clinically from those caused by Norwalk virus.^{116,511} Subclinical infections with Norwalk or Hawaii virus have been observed under experimental as well as natural conditions.

Of 16 volunteers who developed illness following Norwalk or Hawaii virus infection, 14 developed transient lymphopenia.¹¹⁵ This was attributed to a redistribution of circulating lymphocytes to the site of viral infection in the small intestine.

The lymphocytes remaining in the circulation responded normally or exhibited an exaggerated response to mitogenic stimuli.

Clinical manifestations observed in 38 outbreaks associated with NV included the following (expressed as the median percentage of patients): nausea (79%), vomiting (69%), diarrhea (66%), abdominal cramps (30%), headache (22%), fever (subjective) (37%), chills (32%), myalgias (26%), and sore throat (18%).²¹⁶ Bloody stools were not reported. Vomiting occurred more frequently than diarrhea in children, whereas in adults the reverse was observed. The duration of illness in 28 outbreaks ranged from 2 hours to several days, with a mean or median of between 12 and 60 hours in 26 of the 28 outbreaks. In six outbreaks, illness lasted more than 3 days in up to 15% of the affected individuals. The attack rates did not differ significantly with age or sex in six outbreaks in which this was analyzed.²¹⁶

A 2-year study in children (5 years of age or younger) compared the severity of acute diarrheal episodes caused by noroviruses with rotaviruses in hospital emergency and outpatient settings; most cases for both viruses ranged from moderate to severe, although illness was overall less severe for norovirus-infected individuals.³⁵⁴ The clinical course of norovirus illness in preterm infants has been reported to include a distended abdomen and symptoms such as apnea or a sepsis-like appearance: vomiting was not a predominant symptom in these patients.¹⁹ Noroviruses have been reported as associated with the following rare conditions or sequelae: convulsions,^{72,319} encephalopathy,^{196,356} and necrotizing enterocolitis.⁴⁴⁵

DIAGNOSIS

Differential

An analysis of the common features of 38 NV outbreaks indicates that a provisional diagnosis of illness by the noroviruses can be made during an outbreak if the following criteria are met: (a) bacterial or parasitic pathogens are not detected, (b) vomiting occurs in more than 50% of cases, (c) the mean or median duration of illness ranges from 12 to 60 hours, and (d) the incubation period is 24 to 48 hours.²¹⁵ These so-called Kaplan criteria were found to be 99% specific and 68% specific for the provisional diagnosis of a norovirus outbreak when re-evaluated with samples confirmed as norovirus positive.⁴⁷⁶

Differential diagnosis of sporadic norovirus illness in individual patients is difficult, due to shared clinical features (see Clinical Features) with a wide range of enteric pathogens and disease syndromes.

Laboratory

Reverse Transcriptase-Polymerase Chain Reaction

Currently, RT-PCR is the most widely used technique for detection of noroviruses.²³ With this method, noroviruses can be detected in clinical specimens (feces or vomitus) and contaminated food, water, or fomites. The application of real-time quantitative (q) RT-PCR has gained widespread use because it allows rapid detection as well as comparison of viral RNA levels.^{209,473} There are several considerations for optimal performance of RT-PCR techniques.²³ First, the viral RNA extraction procedure should allow the purification of an RNA template that is nondegraded and free of inhibitors of

the RT-PCR reaction. Internal RNA controls can be used in the assay of clinical and environmental samples to avoid false-negative results.^{370,415} Second, the choice of primers is important, because considerable genetic diversity exists among circulating strains. Several primer pairs have been described that were deduced from highly conserved regions of the RNA genome (usually the polymerase region).⁴⁸⁴ RT-PCR, coupled with sequence analysis of the amplicons, has been used extensively to detect and characterize noroviruses in various outbreaks (see Molecular Epidemiology). Norovirus identification is increasingly included in multiplex assays that detect a wide array of enteric pathogens, facilitated by an accumulating norovirus database that has allowed the design of broadly reactive primers and probes.^{160,197,278,424,510}

Immunoassays

Immunoassays for the detection of noroviruses have been developed that employ hyperimmune antisera prepared against rVLPs.^{201,203} Although sensitive, these assays are often highly specific for the immunizing VLP.^{149,200,203,212} Progress has been made in the development of norovirus-specific and cross-reactive monoclonal antibodies^{168,178,181,236,267,270,368,425,514} for use in enzyme-linked immunosorbent assays (ELISAs) that can detect viral antigen in clinical specimens; commercial diagnostic ELISA kits are now available.

The ELISAs that use rVLPs as antigen are specific, sensitive, and efficient for detecting infection with the human caliciviruses and have been used in several large-scale sero-epidemiologic studies (see Prevalence and Seroepidemiology). The Norwalk rVLP ELISA has been shown to detect broadly reactive antibody responses in volunteers given NV, Hawaii virus, or Snow Mountain virus, although the maximal response was observed in volunteers challenged with NV.^{149,154,330,471} Thus, it is impossible to identify the antigenic type of an infecting norovirus strain by serologic analysis because of the cross-reactive antibodies detected by ELISA.^{32,349} The demonstration of an antibody response in 50% or more of the individuals involved (or examined) in an outbreak to a calicivirus antigen is strong evidence linking the virus with the outbreak.²¹⁶

PREVENTION AND CONTROL

Treatment

The noroviruses characteristically induce a mild, self-limited gastroenteritis that normally resolves without complications.^{43,111,112,113,206,442,511} As noted, hospitalization for severe dehydration, although rare, can occur with norovirus gastroenteritis. Oral fluid and electrolyte replacement therapy is usually sufficient to replace fluid loss.^{96,380,477} Oral rehydration therapy should not be administered to patients with depressed consciousness because of the possibility of fluid aspiration. Parenteral administration of fluids may be necessary, however, if severe vomiting or diarrhea occurs.

Oral administration of bismuth subsalicylate after onset of symptoms significantly reduced the severity and duration of abdominal cramps during experimentally induced norovirus illness in adults.⁴⁴² In addition, the median duration of gastrointestinal symptoms was reduced from 20 to 14 hours. The number, weight, and water content of stools, as well as the extent of virus excretion, were not significantly affected by

TABLE 20.5 Various Treatment Protocols Tested in Normal and Immunocompromised Patients with Norovirus Gastroenteritis

Patient status at time of norovirus illness	Age	Norovirus treatment	Dose or modification of Immunosuppressive therapy (IST)	Reported outcome ^b	Reference
Normal	Adult	Bismuth subsalicylate	420 mg	Reduced abdominal cramping	(442)
Normal	12–60 years	Nitazoxanide	Oral, 500 mg, 2× x daily	Shorter duration of illness	(402)
AML	43 years	Nitazoxanide	Oral, 500 mg, 2× daily	Improvement	(427)
Immunocompromised	All ^a	Immunoglobulin	Oral, 25 mg/kg, 4× x daily	Decreased stool output	(131)
HIV	36 years	Immunoglobulin	IV, 400 mg/kg, 1× daily	Minimal 2-day improvement	(504)
Stem cell/lung transplant	56 years	Modify IST	Drug switch	Improvement	(46)
Intestinal transplant	<2 years	Modify IST	Dose reduction	Improvement	(223)
Renal transplant	Adult	Modify IST	Dose reduction	Improvement	(401)
Renal transplant	Adult	Modify IST	Dose reduction	Improvement	(412)

AML, acute myelogenous leukemia; HIV, human immunodeficiency virus; IST, immunosuppressive therapy.

^aTwo study groups: one with average age of 2 years old, the other with male adults.

^bLong term follow-up information unavailable for most patients.

treatment. The use of various medications for symptomatic treatment of acute diarrhea in infants and young children (aged 1 month to 5 years) was reviewed: bismuth subsalicylate, loperamide, anticholinergic agents, adsorbents, or Lactobacillus-containing compounds were not recommended by the American Academy of Pediatrics and, in addition, the use of opiates as well as opiate and atropine combination drugs was contraindicated.³⁸⁰

Although direct-acting antivirals for the treatment of norovirus gastroenteritis are not yet available, treatment protocols implemented for other pathogens have been evaluated in a small number of individuals with norovirus disease, with varying success (Table 20.5). Improvement in chronic norovirus diarrhea has been reported in immunocompromised patients following reduction in immunosuppressive therapy (IST) drugs; however, careful monitoring of these patients is required (Table 20.5). Efforts are in progress to develop antiviral drugs to target specific stages of the norovirus life cycle, but their safety and clinical efficacy have not been established.^{188,229,392,397}

Vaccines

A vaccine for the control of norovirus gastroenteritis is not yet available, but a promising efficacy study in adult volunteers has shown recently that administration of Norwalk virus rVLPs as vaccine provided protection against illness when vaccinees were challenged with Norwalk virus.²² Additional work will be needed to determine the number of antigenic components required to provide protection against a broad range of norovirus antigenic types and variants. Various routes of administration, formulations, and expression systems for rVLPs (or subunit forms) are under investigation.^{27,28,48,122,163,451,452,454,456,460} A safe and effective vaccine could reduce the incidence of epidemic viral gastroenteritis. A vaccine would be of special importance to college students, military personnel, nursing home residents, and individuals in various institutional settings. In addition, it might reduce the number of episodes of severe gastroenteritis in infants and children. Although norovirus gastroenteritis tends to be a mild illness, a reduction in diarrheal episodes may be especially important in the debilitated, mal-

nourished infant, because it has been suggested that repeated diarrheal episodes may be a precipitating factor in the development of malnutrition through sequential damage to the intestinal mucosa.³⁰⁸ The impact of norovirus infection on normal gastrointestinal microflora or underlying disease conditions,⁵⁹ when elucidated, may provide additional data to support norovirus immunoprophylaxis.

Infection Control

Specific methods are not available for the prevention of human calicivirus infection or illness. Outbreak management generally focuses on containment by the prevention of spread to other areas by ill or exposed individuals, frequent handwashing, and effective environmental decontamination.^{8,69,88,226,249,293,469,477}

The noroviruses are generally resistant to detergent or ethanol-based cleaning of environmental surfaces and fomites and require additional chemical disinfection.^{29,119,477} Reliance on the use of alcohol-based hand sanitizers over handwashing has been reported to actually increase the risk of norovirus transmission and infection in patient care settings.^{44,486} Effective disinfectants have been reported to include hypochlorite at 5,000 ppm (domestic bleach is approximately 5% sodium hypochlorite and can be used as a 10% solution), hydrogen peroxide-based cleaners, and phenolic-based cleaners.^{29,477}

Special care must be given to the hygienic processing of food in view of the frequent occurrence of food-borne outbreaks.^{240,475} Depuration of oysters does not adequately clear tissues of NV,^{15,159,416} and recent studies have shown that NV binds to oyster tissues via carbohydrate structures similar to those of human histo-blood group antigens.^{259,294} Precaution must be taken to prevent contamination of oyster beds with feces, vomitus, or sewage treatment plant effluent. Measures that increase the purity of drinking water or swimming pool water should also decrease the frequency of outbreaks.²⁸² Various technological processes are under development to inactivate noroviruses in agricultural food products and shellfish prior to market^{183,230,243,264,333}; human volunteer studies remain important in establishing their efficacy in the absence of an *in vitro* infectivity assay for the human strains.³⁹¹

PERSPECTIVE

Caliciviruses are a highly diverse and evolving family of single-stranded RNA viruses. Because these viruses have a proven ability to persist silently in nature, next-generation pathogen discovery techniques, such as deep sequencing, are sure to uncover many new host species for these viruses. Rabbit hemorrhagic disease virus remained undetected as a pathogen until its sudden emergence as the etiologic agent of a deadly rabbit hemorrhagic disease three decades ago. Murine norovirus, likely present in laboratory mice for decades, was discovered only when genetically engineered laboratory mice lacking a functional innate immune system developed unexplained illness and died, thus prompting investigation. Even recognized calicivirus pathogens may shift suddenly in virulence, as shown by the recent emergence of lethal “virulent systemic” FCV strains. Human GII.4 noroviruses, currently the predominant genotype, periodically undergo genetic drift to cause sharp increases in the number of global gastroenteritis outbreaks, affecting millions.

The diversity and rapid evolution of viruses in the *Caliciviridae* present a constant challenge in the management of disease and in the development of vaccines, and noroviruses are no exception. Human norovirus research is complicated even further by the continued absence of a fully permissive cell culture system, thus hindering the ability to determine serotypic diversity. Despite this stubborn, lingering technical obstacle, important strides have been made in the last few years, and more are on the horizon. Norovirus vaccines containing antigens from the major capsid protein, VP1, have advanced in clinical trials, and the first demonstration of vaccine efficacy has been achieved. The serious nature of prolonged norovirus shedding and illness in immunocompromised patients has become apparent, and intense efforts are in progress to identify an effective antiviral drug. Drug development for human noroviruses is facilitated by the availability of molecular biology-driven tools such as recombinant enzymes expressed from cDNA clones and a human norovirus replicon-bearing cell line. These tools, coupled with the investigation of caliciviruses that grow in cell culture such as feline calicivirus and murine norovirus, each with powerful reverse genetics systems, are bringing the field closer to the realization of effective approaches for norovirus control. The next few years should be remarkable.

Perspectives

Acknowledgments

The family *Astroviridae* includes human and animal astroviruses that show icosahedral morphology; they are nonenveloped and their genome is composed of plus-sense, single-stranded RNA (ssRNA), with three open-reading frames, whose organization distinguishes them from other virus families.

Astroviruses (AstV) have been isolated from a variety of animal species. In most mammals, astrovirus infections are associated with gastroenteritis. In particular, human astroviruses (HAstV) have been found to be the second or third most

common cause of viral diarrhea in young children and cause of sporadic gastroenteritis outbreaks. Avian AstV, on the other hand, have been linked with more severe intestinal and extraintestinal manifestations of disease.

HISTORY

The term *astrovirus* was coined by Madeley and Cosgrove in 1975 to describe small, round viruses with a distinctive five- or six-pointed, star-like appearance (astron, *star* in Greek) of about 28 to 30 nm in diameter.⁸⁶ They were observed by direct electron microscopy (EM) in the stools of infants hospitalized with diarrhea and in outbreaks of gastroenteritis in newborn nurseries (Fig. 21.1). Subsequently, viral particles of similar size and morphology were identified by EM in association with gastroenteritis in a wide variety of young mammals and birds.

An important milestone was achieved in 1981 when Lee and Kurtz reported the isolation and passage of HAstV in primary cell cultures.⁸² This achievement led to the recognition of five HAstV serotypes in 1984,⁷⁹ development of an enzyme immunoassay (EIA) to detect viral antigen in the late 1980s,⁶⁰ and confirmation of its medical importance.⁶¹ The molecular characterization of astrovirus isolates subsequently permitted the recognition of 8 serotypes of HAstV and the design of molecular probes for use as diagnostic tools. Metagenomic approaches have allowed the identification of novel AstV from humans and animal species in recent years.^{16,33,35,115} The efficient propagation of HAstV in cell lines¹⁴⁷ and of turkey isolates in animal models.⁷² has further advanced our knowledge of the molecular and structural biology, as well as of pathogenesis of these viruses.

CLASSIFICATION

The general organization of the astrovirus genome places the open reading frames (ORF) encoding the nonstructural proteins at the 5' end, and the ORF encoding the structural proteins at the 3' end. Distinctive features of this family include the morphology of viruses,¹¹⁶ the lack of an RNA-helicase domain encoded in the genome, and the usage of a ribosomal frameshifting mechanism to translate the RNA-dependent RNA polymerase (RdRp).⁶⁵

Astroviruses were originally classified into genera and species based only on the host of origin; however, recent characterization of novel AstV has shown that isolates from different animal species can be genetically similar, while genetically

diverse viruses can be isolated from the same animal species.^{69,85,152} These findings have led to a proposed new classification scheme based on the amino acid sequence of ORF2 (Astroviruses Study Group, 9th Report ICTV, 2010),¹⁷ which encodes the capsid polyprotein and represents the most variable region of the genome (see below). Two genera are distinguished within the *Astroviridae* family: *Mamastrovirus* and *Avastrovirus* (Fig. 21.2). Viruses belonging to the genus *Mamastrovirus* include isolates from a number of mammals, including humans, pigs (PAstV), cats (FeAstV), minks (MAstV), sheep (OAsV), calves (BoAstV), dogs (CaAstV), bats (BAstV), rats

(RAstV), deer (CcAstV), and marine mammals, such as sea lions (CSIAstV) and bottlenose dolphins (BdAstV), among others. This genus includes two genogroups, GI and GII, with 10 and 9 genotype species, respectively. Both genogroups comprise viruses from human and animal origin. Of note, recently identified human viruses are very similar to animal isolates, such as mink and sheep,⁶⁹ among others. HAstV previously classified within one species that comprised serotypes 1 to 8 (based on their reactivity to hyperimmune sera; HAstV-1 to -8) are now included in the proposed genotype G1 of genogroup I. The genetic diversity found among pig,⁸⁵ bat,¹⁵² and human⁶⁹ isolates places them into highly divergent groups, suggesting that they have different ancestors that probably emerged during interspecies transmission.⁸⁵

Viruses from the genus *Avastrovirus* include isolates from turkeys (TAstV), ducks (DAstV), chicken (CAstV), and guinea fowl. This genus includes two proposed species in genogroup GI (GIA, GIB) and one in genogroup II (GIIA). Similarly to canonical HAstV, members of some of these species can be distinguished by serology, indicating the existence of viral serotypes in some, such as in TAstV-2 and ANV.^{132,134} In general, avastroviruses show higher diversity than mamastroviruses.

VIRION STRUCTURE AND COMPOSITION

Virion Structure

Ultrastructural analysis by EM of human viruses propagated in cell culture in the presence of trypsin revealed icosahedral particles of 41 nm, with spikes protruding from the surface.¹¹⁶ The star-like form of the particles was observed only after alkaline treatment. Recent studies by cryo-EM and image processing of trypsin-treated and untreated HAstV particles confirmed the spiked icosahedral structure of virions (Fig. 21.3) (K. Dryden et al.,

FIGURE 21.2. The *Astroviridae* family includes two genera with two genogroups each. Virus species are classified based on the ORF2 amino acid sequence distances. (Classification proposed by the Astroviruses Study Group, 9th Report ICTV, 2010.¹⁷)

FIGURE 21.3. Three-dimensional reconstruction of HAdV obtained by cryo-electron microscopy. (Courtesy of K. Dryden, University of Virginia.)

unpublished results). Remarkable differences are observed between the two types of particles. The untreated virus, 46 nm in diameter, contains 180 copies of a single protein of 70 kd arranged in a $T=3$ icosahedral symmetry. Two kinds of spikes, localized at two- and fivefold vertices, can be observed in these particles. Two protein layers can be distinguished. The internal layer forms the capsid core and is almost identical to that of treated particles, at the highest resolution reached (23–25 Å); however, the distal layer that forms the spikes shows dramatic changes after trypsin treatment. This treatment results in the cleavage of the 70-kd protein into three polypeptides that is required for virus infectivity (see below). The main difference between the two types of particles is the number of spikes observed, more likely due to disordering of the projections located around the fivefold vertices in the trypsin-treated virions (K. Dryden et al., personal communication).

Virion Composition

Astrovirus particles are formed by the viral genome surrounded by an icosahedral capsid formed by a single protein of 70 to 90 kd, or by at least three proteins in the range of 25 to 34 kd, depending on the extent of proteolytic processing of the virion.^{12,93,119} Extracellular particles, released from HAdV-8 infected cells, are formed by protein VP70, which results from the intracellular processing of VP90, the full-length primary protein product encoded in ORF2⁹⁴ (see below). Fully

infectious particles obtained by exhaustive treatment of the virus with trypsin are constituted by three proteins, in the range of 32–34, 27–29, and 25–26 kd, depending on the virus strain, with the last two proteins overlapping in sequence.^{93,119} Thus, proteins of different size (between 24 and 90 kd), probably representing final and intermediate cleavage products, can be found in particles of HAdV.¹² The size of some of the proteins identified in animal viruses is similar to that of proteins found in human strains; thus, PAstV contains proteins of 31, 30, and 36 kd,¹²⁵ and OAstV contains two proteins of approximately 33 kd⁵⁸; however, PAstV also contains proteins of 39 and 13 kd,¹²⁵ not usually detected in mature HAdV particles. An isolated report indicates that HAdV particles may contain a small protein of 5.2 kd, but its nature was not established.⁷⁸

In addition to proteins derived from ORF2, proteins coded by ORF1a have been suggested to be present in viral particles, since antibodies to purified HAdV-1 virions recognize a recombinant protein containing amino acids 757 to 899 of nspl a.⁸⁹

GENOME STRUCTURE AND ORGANIZATION

Astroviruses have an ssRNA genome of positive polarity [ssRNA(+)] (Fig. 21.4) that varies in length from 6.17 kb for the human strain MLB-1³³ to 7.72 kb for DAdV-2,³⁷

FIGURE 21.4. Genome organization of human astrovirus. The genomic RNA, approximately 6.8 kb, contains three recognized open reading frames (ORF1a, ORF1b, and ORF2). ORF-X has been proposed as functional, given its conservation among AstVs. The genome contains three elements conserved among all members of the family: the frameshift signal (blue square), the sequence upstream of ORF2 that putatively acts as promoter for synthesis of the subgenomic (sg) RNA, and the stem-loop at the ORF2 3' end. Also shown are the insertion/deletion (in/del) region (red square) and the presence of a poly(A) tail at the 3' end.

FIGURE 21.5. Conserved sequences upstream of the ORF2 initiation codon that might represent the promoter for sgRNA synthesis. Red letters indicate those completely conserved among viruses of the same genus; the ORF2 initiation codon is underlined. Viruses within each genus have a different consensus sequence.

excluding the poly(A) tail at the 3' end (e-Table 21.1 and e-Fig. 21.1). The RNA extracted from AstV particles, as well as RNA transcribed from a full-length genomic copy of complementary DNA (cDNA) clone, are able to initiate a productive infection in cultured cells,⁴² although with different efficiencies. The viral genome includes 5' and 3' untranslated regions (UTRs), and three ORFs of variable length in different isolates (e-Table 21.1). The two ORFs located towards the 5' end of the genome, designated ORF1a and ORF1b, encode nonstructural proteins that are presumed to be involved in transcription and replication of the virus genome, based on the sequence motifs they contain (see below). Variation of the ORF1a length in HastV is mainly due to insertions or deletions (in/del regions) present near the 3' end of ORF1a.^{55,144} The third ORF, found at the 3' end of the genome and designated ORF2, encodes the capsid polypeptide. ORF1a and ORF1b overlap in 10 to 148 nucleotides (nt) in the genome of mammalian viruses, and between 10 and 45 nt in avian viruses. The overlapping region contains an essential signal for translation of the viral RNA polymerase (encoded in ORF1b) through a frameshift mechanism⁶⁵ (see below).

Two positive-sense RNA species have been identified in astrovirus-infected cells: the full-length genomic RNA (gRNA), and a subgenomic RNA (sgRNA) of ~2.4 kb¹⁰⁴ (see below, Transcription/Replication section). Based on the transcription initiation site determined for the sgRNA in HastV-1 and HastV-2,^{103,146} ORF1b and ORF2 overlap in 8 nt; however, the length of this overlapping may vary, and it is not present in DastV; rather, it is 24 nt apart in this virus.³⁷ The highly conserved sequence around the ORF2 start codon has been suggested to be part of the promoter for synthesis of the sgRNA,⁶⁸ as described for alphaviruses; however, this region differs in length and sequence between mammalian and avian viruses (Fig. 21.5). This conserved sequence shows partial identity with the 5' end of the gRNA,⁶⁸ suggesting that it has an important role for the synthesis of both gRNA

and sgRNA. Analysis of recombinant AstV isolated from different species has identified this region as a hot spot for recombination.^{132,140,148} Of note, the terminal 19 nt of ORF2 and the adjacent 3' -UTR are highly conserved among most

FIGURE 21.6. Conserved sequence and secondary structure at the 3' end of the ORF2 sequence. The relative position of these sequences is indicated in the upper diagram. Red letters on the sequence comparison indicate conserved nucleotides. The stop codon is underlined in the sequence and in red letters in the stem-loop structures. Although some strains lack this sequence conservation, such as ANV and HastV-MLB1, a stem-loop structure in this region is also predicted.

FIGURE 21.7. Nonstructural proteins predicted from the nucleotide sequence of ORF1a and ORF1b. NBM, nucleotide binding motif; CC, coiled-coil; v-Pro, viral protease; VPg, viral protein attached to the genome; in/del, insertion/deletion; DD, putative death domain; IRE, immune reactive epitope; RdRp, RNA-dependent RNA polymerase.

AstV, and similarities have been observed in the sequence and folding of the 3' -UTR of viruses from other families, such as avian infectious bronchitis virus (a coronavirus), a dog norovirus, and equine rhinovirus serotype 2 (a picornavirus),^{85,101} suggesting that it is relevant for astrovirus genome replication (Fig. 21.6).

ORF1a and ORF1b

The polypeptide encoded by ORF1a (nsp1a) is 874 to 936 amino acids (aa) in length in most mammalian viruses, although it can be as short as 787 in a human isolate and can reach 1,240 in avian viruses (e-Table 21.1). Five to six helical transmembrane motifs followed by a viral serine protease motif (v-Pro) are predicted in nsp1a⁶⁸ (Fig. 21.7). The v-Pro has features consistent with trypsin-like proteases, with a serine at the third catalytic amino acid residue.¹³¹ A viral protein genome-linked (VPg) encoded downstream of the protease motif has also been predicted based on its similarity with the VPg of calicivirus³; however, its synthesis in astrovirus-infected cells has not been investigated. Two predicted coiled-coil structures are present in nsp1a, one just upstream of the first helical transmembrane motif, and the second one downstream of the protease motif, suggesting that some protein products of nsp1a might form oligomers.⁶⁸ One region containing insertion/deletions (in/del), located downstream of the VPg motif, was related to the efficiency of HAstV to synthesize viral RNA species and to adaptation to cultured cells^{55,144}; however, it is not known whether the RNA sequence or the encoded protein is involved in modulating those events. ORF1b encodes a polypeptide of 515 to 539 aa that contains motifs of an RdRp, which are similar to RdRp of picornaviruses, caliciviruses, and certain plant viruses.^{3,65}

Regions that could potentially encode an RNA helicase and a methyltransferase have not been identified in the astrovirus genome.⁶⁵ Given the putative existence of a VPg, the absence of a methyltransferase could be understandable; however, the absence of an RNA helicase domain is unusual for a plus-strand RNA virus with a genome length of more than 6,000 nt, like astrovirus.⁶⁵ The amino terminus of nsp1a shows similarity with an NTP binding motif of some helicases,³ but lacks other motifs, such as the substrate binding and NTP hydrolysis domains present in these enzymes.¹³⁵

ORF2

The largest sequence variability in the astrovirus genome is found in ORF2, which codes for the virus structural polyprotein. This polypeptide varies from 672 to 851 aa in length in TastV-1 and a porcine strain, respectively. In general, the ORF2 of avian viruses codes for shorter polyproteins (e-Table 21.1). The N-terminal half of the polyprotein is more conserved than the C-terminal domain, encompasses a region of basic character that is conserved among astroviruses,^{67,142} and is thought to interact with the genomic RNA in the virion.⁴³ On the other hand, the C-terminal half of the protein shows considerable sequence variability among astroviruses isolated from different species, even among different isolates from the same animal species; the sequence of this region defines the serotypes in HAstV (Fig. 21.8). A delimited region with abundant insertion or deletions among different astroviruses is also present in the carboxy half of the capsid protein.¹⁴² The acidic character of a small portion of the protein, located close to the carboxy terminus (residues 649 to 702 for HAstV-8), is highly conserved among all members of the *Astroviridae* family.⁹² The last five amino acid residues at the C-terminal end

FIGURE 21.8. Features of the structural protein. The primary ORF2 product (named VP90 in HAstV-8), contains two domains that can be distinguished by their degree of conservation: the N-terminal domain is highly conserved and forms the core of the capsid, while the hypervariable C-terminal domain forms the spikes of the virus particle. VP90 contains basic and acidic regions that are highly conserved among all AstVs characterized. The diamond in the conserved domain indicates a lethal mutation identified in HAstV-1 and the black arrows indicate motifs recognized by caspases, important for virus maturation and cell egress.

FIGURE 21.9. Replication cycle of HAdV. See details in the text.

are conserved, particularly among human and some other mammalian strains.

The conserved domain of the structural protein forms the capsid core of the particle, whereas the hypervariable C-terminal domain forms the spikes of the virion; thus, this last domain is predicted to participate in the early interactions of the virus with the host cell.⁷⁶

An alternative ORF (named ORF-X) of 91 to 122 codons overlapping ORF2 in a +1 reading frame has been described in all HAdV and some other mammalian viruses³⁶ (Fig. 21.4). Its initiation codon, usually located 41–50 nt downstream of the ORF2 AUG, is placed in a better Kozak's consensus sequence than that of ORF2, and might be translated through a leaky scanning mechanism. It remains to be determined whether ORF-X is actually translated and, if it is, its significance for virus replication.

STAGES OF REPLICATION

Attachment and Entry

Studies directed toward understanding the early interactions of astroviruses with their host cells have been limited; however, a general view of the replication cycle can be depicted (Fig. 21.9). Cell receptor molecules for these viruses have not been identified. Different HAdV strains show different tropism in cultured cells¹⁹; thus, it is likely that their initial interactions with the host cells might be different.

The infectivity of human astroviruses is greatly enhanced (3 to 5 logs) by, and probably requires, the treatment of the virus particles with trypsin.^{8,93,119} Although the proteolytic pathway of VP70 processing present in the virion has been elu-

cided for HAdV-8,⁹³ the mechanism by which this treatment enhances virus infectivity is still unknown. Trypsin cleavage of the precursor polypeptide induces drastic structural changes in the particles⁸ (Fig. 21.3) and the generation in HAdV-8 of three final products: VP34, VP25, and VP27 (see details in the Protein Synthesis and Processing section). VP34 represents the conserved domain and forms the capsid core, while both VP25 and VP27 form the spikes on the virion surface. In spite of its high variability, VP25 contains two conserved structural motifs that have been suggested to be involved in the interaction of the virus with the host cell, one of which includes residues Lys455, Ser554, Thr575, and Glu610, predicted to interact with oligosaccharide moieties that could act as cell receptors or co-receptors (Fig. 21.10) (Dr. Y.J. Tao, unpublished data). Antibodies that recognize the spike proteins VP25 and VP27 neutralize virus infectivity,^{9,119} probably by blocking virus binding.

Early studies on HAdV entry in HEK-293 Graham cells using endocytosis-blocking agents (ammonium chloride, methylamine, and dansylcadaverine), as well as ultrastructural analysis, indicated that an endocytic, coated pit-dependent pathway is used by the virus to enter cells.³⁰ Recently, a clathrin-dependent endocytosis was confirmed to be a functional pathway for the entry of HAdV-8 into Caco-2 cells (unpublished results).

The interaction of HAdV with the host cell provokes activation of the ERK1/2 signaling pathway within the first 15 minutes after virus attachment.¹⁰⁷ Although the mechanism for this activation is unknown, it was independent of virus replication, suggesting that this pathway is triggered during virus binding or entry into the cell. Accordingly, ERK1/2 seems to be required at early times to establish a productive infection,

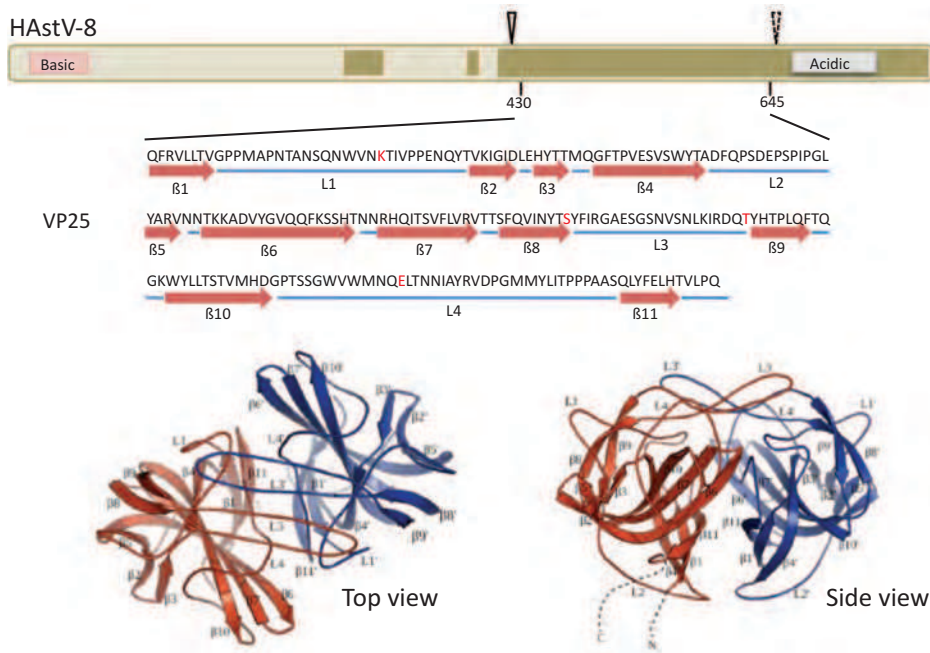

FIGURE 21.10. Three-dimensional structure of the spike protein VP25.

The hypervariable region of HAstV-8 VP90, including residues 430 to 645, crystallized to 1.8 Å resolution as a dimer. The upper diagram shows the relative position of the crystallized protein; the cleavage carried out by trypsin is indicated (arrowheads, as in Fig. 21.15). Amino acid residues Lys455, Ser554, Thr575, and Glu610 (red in the sequence) are strictly conserved in all eight HAstV serotypes, and have been proposed as potentially interacting with cell surface carbohydrate motifs during the early virus–cell interactions. Top and side views of the spike are shown. (Courtesy of Dr. Y. J. Tao, Rice University.)

since inhibitors of this kinase blocked synthesis of viral proteins and RNA and, consequently, reduced virus yield. HAstV also induce an increase in the epithelial barrier permeability that is independent of virus replication, apparently due to an interaction between the capsid protein and the cell surface.¹⁰⁵ It has been suggested that HAstV could trigger tight junction instability to reach putative receptors present in the basolateral membrane; however, the fact that the increase in permeability is observed after at least 16 hours of addition of the virus suggests that more than a requirement for infection, it is a consequence of the cellular transduction signal pathways induced by the virus.

Uncoating

The mechanism through which the viral genomic RNA is released from the infecting virus particle into the cytoplasm for translation, the cell site where it occurs, and the cellular and viral factors involved in this event are unknown.

Translation

No detectable changes in cellular protein synthesis are observed upon HAstV infection. As do most cellular mRNAs, astroviral RNA contains a polyA tail at the 3′ end, but the presence of a cap structure at its 5′ end has not been described. Since a VPg has been suggested to be encoded in astrovirus ORF1a,³ this protein could modulate the translation of viral mRNAs by interacting with translation initiation factors, as has been described for other viruses, such as calicivirus.^{23,29}

Nonstructural Polyproteins Synthesis and Processing

After uncoating, the gRNA is translated into nonstructural proteins that are produced as polyprotein precursors and subsequently proteolytically processed into smaller proteins. ORF1a directs the synthesis of protein nsp1a (of about 100 kd), whereas protein nsp1ab (160 kd) is derived from both ORF1a and ORF1b, through a frameshift mechanism of translation

(see below). Proteins nsp1a and nsp1ab are apparently processed co-translationally at their amino terminus, so that the expected full-length proteins are not, or very rarely, observed in HAstV-infected cells (Fig. 21.11). Information regarding processing of the nonstructural polyproteins has been obtained by *in vitro* translation, transient expression of cDNA clones, and analysis of HAstV-infected cells, using antibodies to different regions of nsp1a and nsp1ab.^{41,45,95,145} No specific processing of nsp1a and nsp1ab were observed by *in vitro* translation of cDNA-derived transcripts,⁴⁵ suggesting a requirement for cellular factors.

In HAstV-1-infected Caco-2 cells, Willcocks et al.¹⁴⁵ detected proteins of 74, 34, 20, 6.5, and 5.5 kd with antibodies raised to the predicted C-terminal 298 aa of nsp1a. Proteins of 20 and 74 kd—in addition to products of 88, 27, and 19 kd—were also detected in Caco-2 cells infected with an HAstV-8 strain using antibodies to several regions of nsp1a.⁹⁵ The 19- and 20-kd proteins likely represent the most N-terminal products of nsp1a, apparently cleaved out by a cellular protease, probably a signalase, because it is produced by *in vitro* translation experiments only in the presence of microsomes,⁹¹ it occurs co-translationally,^{41,95} and it is independent of the v-Pro activity.⁴¹ The 27-kd protein represents the v-Pro and probably spans from around amino acid residue 410 to 654 of nsp1a.⁴¹ Proteins of 160, 75, and 38 to 40 kd, and phosphorylated forms of 21 to 27 kd were also detected with antibodies to a synthetic peptide that comprises aa residues 778 to 792 of nsp1a.⁵⁴

Translation of the RdRp occurs through a ribosomal-1 frameshift mechanism in the overlapping region between ORF1a and ORF1b. The signal that modulates this event has two key features, conserved among all astroviruses: a heptameric sequence (AAAAAAC) and the potential to form a downstream stem-loop structure¹⁸ (Fig. 21.12). Translation of heterologous proteins, with the HAstV frameshift signal included, revealed that its efficiency varies between

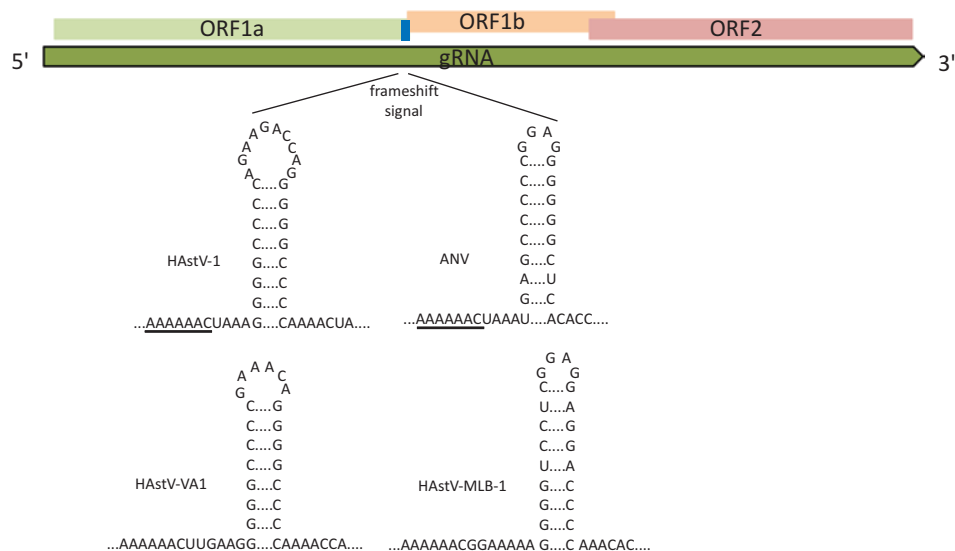

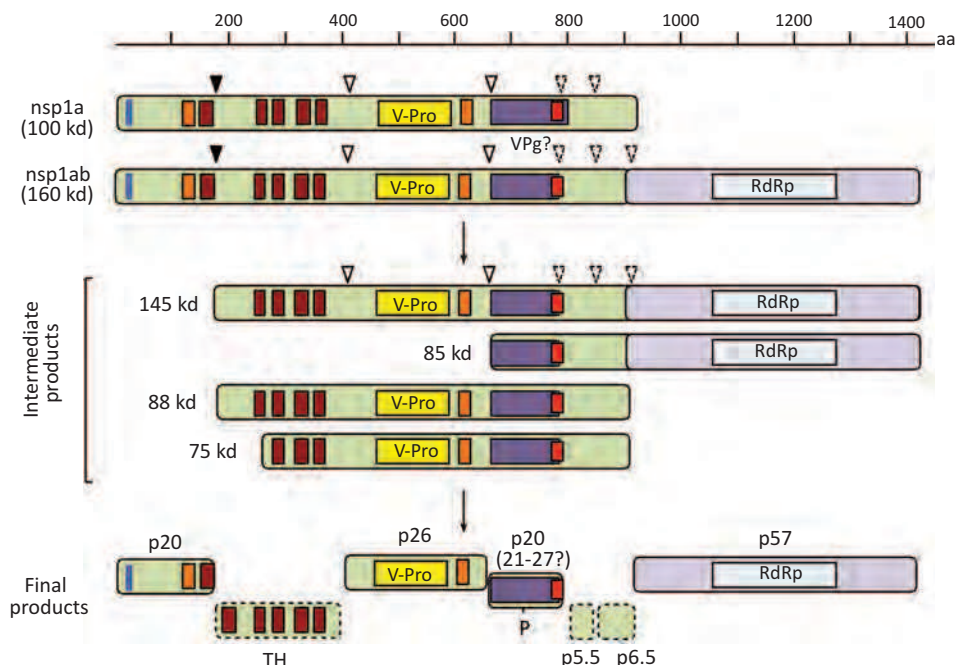

FIGURE 21.11. The frameshift signal (fss) of astroviruses is composed by a slippery sequence (underlined) and a stem-loop structure. The length and sequence of the loop and of the region between the slippery motif and stem-loop structure are not important for its function,¹⁸ as seen for the viruses shown.

7% and 28%, depending on the system in which it was evaluated⁸⁴; however, the efficiency of the frameshift has not been determined in HAsV-infected cells. Antibodies raised to recombinant proteins containing the RdRp motif identified a protein of 57 kD as the final product in Caco-2 cells infected with an HAsV-8 strain.⁹⁵

In summary, proteins of 27, 20, 19, 6.5, and 5.5 kD, as well as the phosphorylated 21 to 27 kD polypeptides, seem to represent the final processing products of polyprotein nsp1a, whereas a 57 to 59 kD protein represents the mature protein derived from ORF1b. The proteins observed of 145, 88, 85, 75, and 34 kD most likely represent intermediate products of the nonstructural protein processing (Fig. 21.11). With excep-

tion of the cleavage that releases the 20 kD most amino-terminal polypeptide, all other cleavages at nsp1a and nsp1ab polypeptides are believed to depend on the v-Pro activity, although only those identified at around amino acid residues 410 and 654 have been confirmed.⁴¹ Crystal analysis of the v-Pro domain (Fig. 21.13) showed that the enzyme contains a basic S1 pocket that recognizes and cleaves acidic residues (Glu and Asp) at position P1.¹³¹ Thus, Asp-413, but not Ala-409, and Glu-654 seem to be the actual residues cleaved by v-Pro on nsp1a. The C-terminal region of nsp1a contains many acidic residues that prevent the prediction of cleavage sites downstream of Glu-654 recognized by the viral enzyme to generate the 6.5 and 5.5 kD products observed.

FIGURE 21.12. Processing of the nonstructural proteins. Nsp1a and nsp1ab are processed by cellular (*closed triangle*) and viral (*open triangles*) proteases. Although only the cleavages around amino acid residues 410 and 654 have been confirmed to be due to v-Pro, indirect evidence that would explain the protein processing products observed suggests that the downstream cleavages (*dashed triangles*) are also due to viral protease. No products from the hydrophobic region have been identified and the smaller products of 5.5 and 6.5 kD have not been mapped into nsp1a (*dotted boxes*).

FIGURE 21.13. Diagram representing the structure of the HAstV-1 viral protease. Residues 432 to 587 of HAstV-1 nsP1a (upper sequence) were crystallized to 2.0 Å resolution. Monomer (left) with the two domains in blue and pink, and the catalytic residues in yellow and red letters is shown on the left. In the dimer (right), two domains of a monomer are colored and the other monomer is in grey. Structure was obtained from Protein Data Bank (ID code 2w5e).

Structural Polyprotein Synthesis and Processing

The structural proteins of HAstV, encoded in ORF2, are synthesized from the sgRNA as a polyprotein precursor of 87 to 90 kd. Studies with HAstV-8 have revealed that the 90-kd primary translation product is intracellularly cleaved at Asp-657 to yield a product of 70 kd (named VP70)⁷ through intermediates of 75 to 85 kd,⁹⁴ whose biological relevance, if any, is unknown (Fig. 21.14). Processing of VP90 to VP70 is carried out by cellular enzymes (caspases) that are involved in apoptotic processes,⁷ and whose activity is triggered during viral infection by an unknown mechanism.^{7,53} The pan-caspases inhibitor Z-VAD-fmk strongly inhibits this processing, whereas specific inhibitors of caspase activity partially block it. On the contrary, some proapoptotic factors—such as TNF-related apoptosis-inducing ligand (TRAIL) and staurosporine, which triggers different apoptotic pathways—enhance the cleavage of VP90 to VP70.⁹⁴ It is believed that caspases are important for processing the structural polyprotein precursor in most, if not all, astroviruses since the caspase-recognition motifs present

at the carboxy-terminal region of VP90 are highly conserved among different strains. For HAstV-8, caspase-3 and caspase-9 seem particularly important for processing VP90; however, other caspases might also be involved, since VP90 is substrate of caspase-8 and caspase-4 *in vitro*.⁷ Also, it cannot be excluded that different caspases are responsible for cleavage of VP90 from different astrovirus strains, since the motifs recognized by caspases in this precursor protein vary among viruses. Of interest, the VP90 to VP70 processing is not required for VP90 to assemble as viral particles, but it is important for the egress of the virus from infected cells^{7,91} (see below).

Extracellular particles of HAstV-8 formed by VP70 are weakly infectious, but its infectivity is strongly enhanced by treatment of the viral particles with trypsin,^{8,93} which is present in the intestinal lumen. Protein VP70 present in the extracellular virion is initially cleaved to yield 41 kd (VP41, the N-terminal product) and 28 kd (VP28, the C-terminal product) polypeptides. VP41 is subsequently cleaved at its carboxy terminus to yield a mature protein of 34 kd (VP34), whereas

FIGURE 21.14. Processing of the structural protein VP90. The primary product of ORF2 is sequentially processed at its carboxy terminus by caspases to generate VP70, the protein present in the extracellular particles. These particles are processed by trypsin to generate protein intermediates of variable size, and the final products VP34, VP27, and VP25. Closed arrowheads represent cleavages carried out by caspases; open, long arrowheads represent cleavages by trypsin. The cleavage sites indicated by dashed arrowheads have not been precisely determined, therefore the carboxy-terminus of the intermediate and final products is unknown.

VP28 is cleaved to final products of 27 and 25 kd (VP27 and VP25, respectively) that share their carboxy terminus.⁹³ Thus, the full infectious virus is constituted by VP34, VP27, and VP25.

The C-terminal products VP25 and VP27 (or VP26 and VP29 in HAsV-2) are recognized by neutralizing antibodies,^{9,119} whereas VP34 (VP32 in HAsV-2) contain cross-reaction epitopes that have been used for diagnosis.⁵⁹ Although not tested, the infectivity of other astroviruses may also depend on trypsin treatment, since sites susceptible to trypsin cleavage are conserved in the capsid protein from avian and mammalian viruses.

Transcription/Replication

Astrovirus RNA synthesis has been poorly studied. Given the structure and organization of the astrovirus genome, it is believed that these viruses follow a strategy similar to that of alphaviruses to replicate and transcribe their genome.⁴⁴ Based on this assumption, the gRNA would be used as a template to synthesize a full-length negative-sense RNA, gRNA(-), which in turn would be used as a template to produce both the full-length gRNA and the sgRNA. These positive-strand RNA molecules are initially observed in HAsV-8-infected Caco-2 cells at 8 hours postinfection (hpi) (Fig. 21.15), indicating that at this time gRNA(-) is already synthesized, although at undetectable levels. In a different study gRNA(-) was detected starting at 9 hpi and it accumulated to 0.7% to 4% of gRNA.⁶⁴ Similarly to alphavirus, it is believed that the viral transcriptase recognizes a *cis*-element that acts as a promoter on gRNA(-) to synthesize the sgRNA, which in the case of HAsV can reach five- to tenfold higher molar abundance than the full length gRNA.¹⁰⁴ A sequence located around the ORF2 initiation codon that is highly conserved among most known astroviruses might represent that promoter (see above, Fig. 21.5).

Synthesis of gRNA(-) and accumulation of gRNA require cell protein synthesis, but not cellular DNA transcription.⁶⁴ v-Pro, RdRp, VP90, gRNA(-), and viral particles have all been found to be associated with internal cell membranes.⁹¹ This suggests that RNA replication and the first steps of morphogenesis are carried out associated with the observed membranous structures that probably derive from the ER, since viral phosphoproteins of 21 to 27 kd, which interact with the

RdRp,³⁸ and are likely involved in RNA replication, localize to this organelle.⁵⁴

Besides v-Pro and RdRp, no specific function has been assigned to the rest of the ORF1a and ORF1b products. Since the 20-kd N-terminal product of nsp1a is cleaved co-translationally, it is likely that the cleavage is carried out by a signalase.⁹⁵ This protein thus might target the replication complexes to membranes, although the predicted region containing highly hydrophobic transmembrane helices (amino acid residues 178 to 409) could also contribute to association of the replication complexes to membranes. A potential VPg has been suggested as possible product of nsp1a,³ just downstream of the protease, opening the possibility that AstV RNA synthesis would be primer dependent. Further studies are required to confirm this hypothesis.

Assembly and Release

The expression of ORF2 in cultured cells using recombinant vaccinia virus²⁸ or baculovirus²² as vectors leads to the assembly of virus-like particles, indicating that the encoded protein is able to assemble in the absence of viral RNA; however, these particles were unstable and showed atypical morphology when purified, indicating a defective assembly.^{22,105}

Virus assembly tolerates some deletion or changes in the 70 N-terminal basic amino acids of VP90/VP70, which are thought to interact with the gRNA in the particles.⁴³ The infectivity of a recombinant virus in which aa residues 11 to 30 were replaced by 8 or 9 amino acids of a foreign sequence reduced to about 50%. In contrast, viruses carrying the same foreign sequence in place of aa residues 31 to 50 of the capsid protein showed a drastic reduction to 0.1% of infectivity. Substituting the 5' C-terminal aa of ORF2 was also very deleterious to virus infectivity.⁴³ A single-point lethal mutation was described in HAsV-1 VP34 (Thr-227 to Ala or Ser),⁸⁸ however, whether the defect on infectivity was due to a defective assembly was not studied.

The ORF2 primary product of HAsV-8, VP90, forms intracellular particles that can be found associated with membranes or in the cytosol.⁹¹ Apparently, VP90 assembles into particles associated with membranous structures, where viral nonstructural proteins and the sense and antisense genomic RNA are also present⁹¹; therefore RNA replication is also thought to occur associated with these structures (Fig. 21.16).

FIGURE 21.15. Astrovirus RNA species and their relative proportion produced during infection of HAsV. Total RNA from HAsV-8-infected cells at a multiplicity of infection of 2 were separated by gel electrophoresis. Ribosomal RNA was detected by staining with ethidium bromide (**upper left**), and viral RNAs by Northern blot with a negative-polarity RNA probe that is able to detect both gRNA and sgRNA (**upper right**). The hours postinfection (hpi) at which each sample was taken is shown. The lower scheme depicts the astrovirus RNA species and their relative amounts in infected cells.^{64,104}

FIGURE 21.16. Model of VP90 processing and virus maturation. See details in the text.

It is believed that rearrangement of internal membranes is induced by AstV infection, since it is observed in intestinal epithelial cells of lambs infected with OAstV but not in uninfected cells.⁴⁸

HAsV infection induces the activation of caspases in Caco-2 cells through an unknown mechanism. Activity of initiator (caspase-8, -9, and -4), and executioner (caspase-3 and -7) caspases is clearly detected at 12 hpi. Apoptotic markers, such as lamin A and poly (ADP-ribose)-polymerase (PARP) cleavage, are also detected at 12 hpi, although cell death is not observed up to 48 hpi, even at high moi.⁷ A putative death domain (pDD), localized downstream of the v-Pro domain (aa residues 620 to 714 of nsP1a), was suggested as responsible for activation of caspases⁵³; however, given that cleavage at Glu-654 by v-Pro would split this putative domain, its role in caspase activation requires further investigation. Recent findings that v-Pro may cleave Asp residues¹³¹ open the possibility that this enzyme might cleave and activate pro-caspases.

Proteolytic processing by caspases of the VP90 assembled into particles, to yield VP70, is required for cell egress of the virus, since inhibitors of these proteases prevents it, while it is promoted by pro-apoptotic factors, such as TRAIL.⁹⁴ It is believed that after their initial assembly associated with membranes, the viral particles formed by VP90 separate from these structures, exposing its carboxy terminus, such that it is now available to caspase cleavage.⁹¹ In addition to its role in cleaving VP90 to VP70, the activity of Cap-3 seems to be required by the virus to exit the cell.⁷ Although the cellular process mediated by this caspase to allow virus egress is not known, the cell death induced by this protease seems not to be necessary; thus, a nonlytic mechanism seems to be involved in the release of HAsV. On the other hand, since a cytopathic effect was observed upon infection with porcine,¹²⁵ and chicken¹⁰ astrovirus strains, these viruses could use more than one mechanism to exit the cell.

PATHOGENESIS AND PATHOLOGY

As a gastrointestinal pathogen, HAsV can be transmitted to a host through the fecal–oral route, as shown by human vol-

unteer studies, but also person to person, as it was found in an outbreak of gastroenteritis in California.⁹⁷ Illness in adults can also be due to exposure to a larger dose of astrovirus or through fomites, and contaminated food or water.^{2,13} In the case of avian viruses transmission is also through a fecal–oral route, facilitated by the large amount of viruses secreted in feces and the usual contact of animals with them, although it has also been proposed to occur by vertical transmission from parents to their offspring.¹³⁷

Mammalian astroviruses affect mainly epithelial cells of the intestinal tract. Histopathologic studies of an immunocompromised child persistently infected, having a pronounced diarrhea, showed that astrovirus infection was limited to the small intestine. Infection involves the mature epithelial cells near the microvilli tips; it was more extensive in the jejunum than in the duodenum, but not in the stomach (Fig. 21.17).¹²² Morphologic abnormalities in the intestine suggested that, despite severe diarrhea, an inflammatory response does not occur. Studies with other mamastroviruses indicate that AstV can infect epithelial cells (OAstV and BoAstV) as well as subepithelial macrophages (OAstV) and M cells (BoAstV) of the small intestine.^{130,150} OAstV particles were observed in vacuoles of the enterocytes, very similar to those found during infection of HAsV in cultured cells. OAstV infection resulted in diarrhea on days 2 to 4 postinfection and a transient villus atrophy and crypt hypertrophy.⁴⁸ Although BoAstV was considered as nonpathogenic because it was unable to induce diarrhea in gnotobiotic animals, inflammatory mononuclear cells above the dome villi were observed on infection with this virus. In addition, the lamina propria was infiltrated with neutrophils and contained cells with degenerate nuclei. Lymphoid-cell depletion was noted in the central region of germinal centers beneath infected dome villi.¹⁵⁰

Astrovirus was recently found as the only pathogen in the central nervous system (CNS) of an immunodeficient patient who died of encephalitis.¹¹⁵ Expression of structural proteins was specifically localized in astrocytes, but not in macrophages or neurons. Infiltration of macrophages and inflammation were found in the CNS of the patient, although evidence of astrovirus infection was not found in gastrointestinal postmortem samples. Of note, the human strain associated with encephalitis

FIGURE 21.17. **A:** Photomicrograph of a jejunal biopsy specimen from a bone marrow transplant recipient with astrovirus infection demonstrating villus blunting, nonspecific alterations in surface epithelial cells and a mixed lamina propria inflammatory infiltrate, but without the presence of viral inclusion bodies (original magnification, $\times 100$). Photomicrographs of **(B)** duodenal and **(C)** jejunal biopsies from a bone marrow transplant recipient with astrovirus infection immunostained with anti-astrovirus antibody and demonstrating progressively more extensive staining of surface epithelial cells, most commonly near the villus tips (original magnifications, $\times 40$ and $\times 100$, respectively). **D:** Electron micrographs of a jejunal enterocyte demonstrating cytoplasmic paracrystalline viral arrays of astrovirus [original magnifications, $\times 32,000$ and $\times 100,000$ (inset)]. (From Sebire NJ, Malone M, Shah N, et al. Pathology of astrovirus associated diarrhoea in a paediatric bone marrow transplant recipient. *J Clin Pathol* 2004;57:1001–1003, with permission.)

was genetically related to a novel human astrovirus associated with an outbreak of gastroenteritis (strain VA1)³⁵ and with celiac disease.¹²⁷ It was also found in feces of five children with nonpoliovirus acute flaccid paralysis,⁶⁹ although it was also present in one healthy child. In addition, an astrovirus strain was found in the CNS of minks suffering from a neurologic disease (shaking mink syndrome) by metagenomics.¹⁶ In this last case, the syndrome was transmitted from infected to healthy animals by inoculation of brain homogenates. These findings suggest that AstV might cause neurologic diseases in mammals; however, the mechanism by which astrovirus could reach the CNS after infecting the gastrointestinal tract is unknown.

Lack of inflammation after intestinal astrovirus infection in humans¹²² and turkeys⁷² and the ability of HAsV to induce apoptosis in cultured cells^{53,94} suggest that this form of pro-

grammed cell death, in which inflammation is not frequently observed, could contribute to gastrointestinal disease. However, more than one mechanism could participate in the disease produced by these viruses since, for instance, inflammation was observed in the CNS upon AstV infection.¹¹⁵ Inflammation was also observed in premature children with necrotizing enterocolitis associated with HAsV, although in this case it was unclear whether inflammation was due to bacteria or HAsV spread.^{5,6}

Structural proteins may also be involved in pathogenesis, since the capsid protein is able to increase the permeability of monolayers of epithelium cells in culture.¹⁰⁵ Apparently, no virus replication is needed for the capsid protein to have this effect, but transduction signals are likely involved since barrier permeability was clearly increased at 20 hours after treatment with inactivated virus or the purified protein, but not earlier.

The HAsV-1 capsid protein binds C1q and mannose-binding lectin, blocking the complement activation through the classical and lectin pathways, respectively. Interaction of the virion with C1q is likely conserved among astroviruses, given the high conservation of the complement system in animals as well as of the region through which the capsid protein interacts with C1q (aa residues 79 to 108).

TAsV-2, isolated from birds with poult enteritis mortality syndrome (characterized by enteritis, growth depression, lymphoid atrophy, immunosuppression, and high mortality rates), has been used as a model to study astrovirus pathogenesis in young turkeys.⁷² Experimental infection of turkeys with TAsV-2 has shown that infectious virus can be recovered from many tissues, including blood, indicating the occurrence of viremia. The intestine, however, appears to be the only organ in which astrovirus replicates in this disease model.¹¹ Turkeys developed diarrhea on days 1 through 3 that persisted through 4 more days. In the intestines, no drastic morphologic changes or apoptosis were observed by light microscopy in infected animals; however, the F-actin distribution pattern changed at the apical region of jejunum tight junctions, which correlated with zones of infected cells. It has been suggested that these changes, together with defects in Na⁺ absorption probably due to modifications of expression and cell distribution of sodium/hydrogen exchangers, might provoke osmotic diarrhea.¹¹⁰ Intracytoplasmic aggregates of astrovirus were found in enterocytes on the sides and base of villi in the ileum and distal jejunum on day 3.

Avian astroviruses may spread to other tissues besides intestine, such as kidney, pancreas, lymphoid organs and liver, causing more severe diseases; however, this effect might depend on many factors, such as animal age and route of infection (vertical or horizontal), maternal antibody levels, size of the infecting dose, virus strain, and the presence of co-infecting pathogens.^{66,128,133,136}

Immunity

Determinants of immunity to astrovirus are not well understood. Symptomatic astrovirus infection is found primarily in two age groups: young children and elderly, institutionalized patients. Indirect evidence suggests that astrovirus-specific antibodies could play a role in limiting infection in the host. The existence of astrovirus serotypes in different animal species, classified mainly on the basis of neutralizing antibody reactivity against the carboxy region of the capsid protein, suggests that antibodies exert immune pressure on the virus.⁷⁰ The biphasic age distribution of symptomatic infection suggests that antibody acquired early in life provides some kind of protection from illness through most of adult life and that immunity to astrovirus wanes late in life. Immunoglobulin therapy of immunocompromised patients with persistent astrovirus infection resulted in virus clearance and diarrhea elimination.¹⁵ However, the role of astrovirus-specific antibodies to clear the virus was not defined because no neutralizing antibodies were measured in the immunoglobulin preparation utilized. On the other hand, bone marrow transplant patients with chronic diarrhea did not respond to the immunoglobulin treatment, although this preparation was demonstrated to have antibodies to the homologous infecting astrovirus serotype.²⁷ Thus, the response of patients to immunoglobulin treatment for virus clearance could be caused by additional unspecific factors more than to astrovirus-specific antibodies.

The normal mucosal immune system could be important in protecting individuals from repeated infections with human astrovirus.¹⁰⁰ T cells that recognize astrovirus antigens in a human leukocyte antigen (HLA)-restricted manner were found to reside in the intestinal lamina propria of healthy adults. These human astrovirus-specific CD4⁺ T cells produced helper T-cell subtype 1 (T_H1)-type cytokines, interferon gamma, and tumor necrosis factor, when activated.

The complement system is one of the initial host responses to pathogens, important in both innate and adaptive immunity. By blocking the complement system,^{51,57} as mentioned earlier, HAsV could alter an effective immune response of the host. However, on the other hand, binding of C1q to the capsid protein already assembled in the virion, if it occurs, could facilitate phagocytosis and elimination of the virus by C1q acting as opsonin.

In animals, the role of the humoral immune response to limit astrovirus infection is also not clear. Koci et al.⁷¹ found that virus replication in small turkeys infected with TAsV was limited, even though the infection did not induce a significant adaptive immune response, evaluated through measurement of a specific increase in the population of CD4⁺ and CD8⁺ T cells. Because there was no protection against TAsV upon secondary challenge, the limitation of virus replication was attributed to an innate response, mediated by production of nitric oxide. In chickens, protective immunity can be conferred by the capsid protein, since inoculation of this protein partially protected animals from disease,¹²³ although the role of humoral and cellular immunity in this partial protection is still unknown.

EPIDEMIOLOGY

HAsV infections have been found worldwide primarily, but not exclusively, in young children with diarrhea. Several studies associate astroviruses with diarrhea in immunocompromised patients, including adults,^{15,25,27,40,50,149} and with necrotizing enterocolitis (NEC) in premature children.^{5,6} Sporadic outbreaks of gastroenteritis caused by astrovirus have been reported among elderly patients⁸³ and military recruits.¹³ Large, food-borne outbreaks, affecting thousands of individuals in Japan, have occurred among school-aged children and adults as well.¹¹² In children, studies in different populations^{26,113} have revealed HAsV as the second most important cause of gastroenteritis, after rotavirus, with incidences varying between 4.2% and 7.3%, although incidences lower than 1% have also been reported. Higher incidences of HAsV have been rarely reported in children with diarrhea, such as in native populations of Brazil and southeast Mexico, with incidences of 56%³⁹ and 28%,⁸⁷ respectively. The age distribution of HAsV can vary depending on several factors; however, in a study carried out in Spain, approximately 80% of the astrovirus infections occurred in children under 3 years of age.⁵⁶ The age-specific HAsV incidences (episodes per year) found in an Egyptian study (0.38 for infants <6 months, 0.40 for infants 6 to 11 months, and 0.16 for children between 12 and 23 months) were similar to those found for rotavirus.¹⁰⁹

Most astrovirus infections in humans are detected in the winter months in temperate regions and in the rainy season in more tropical climates.^{26,141} Both community-acquired and

FIGURE 21.18. Prevalence of HAstV serotypes in children with diarrhea. This graph compiles data from eight studies in different countries with 461 astrovirus-positive samples. (Adapted from Monroe, SS. Molecular epidemiology of human astroviruses, In: Desselberger U, Gray JJ, eds. *Perspectives in Medical Virology. Viral Gastroenteritis*. Vol. 9. Amsterdam: Elsevier, 2003:607–616.)

nosocomial infections, particularly among immunocompromised patients^{25,40} and premature children, have been observed.

Eight serotypes have been mainly described among viruses that circulate in the human population. In general, serotype 1 of HAstV is the most common type found in children¹⁰² (Fig. 21.18), but the predominant serotype can vary with time and location. Thus, in a study in the United Kingdom, 72% of the community-acquired astroviruses encountered between 1975 and 1987 were serotype 1⁷⁸; while in Australia serotypes 1, 3, and 4 were regularly found in a period of 18 years.¹²⁰ In contrast, a longitudinal study of diarrhea in a cohort of Mexican children found that astrovirus serotype 2 was the most common (35%).⁵² In a different study with samples from different geographic regions in Mexico, all eight serotypes, except serotype 5, were found, with serotype 8 being as frequent as serotype 1 in one of the studied regions.⁹⁶ Analyzing AstV from different regions of India, putative recombinant viruses were found to be the most prevalent in children under 24 months of age.¹³⁸ Recombinant viruses containing RdRp and the capsid protein from different canonical HAstV have also been identified in different populations of Kenya.¹⁴⁸

Epidemiologic studies of AstV in the human population have been limited so far to the canonical HAstV serotypes 1 to 8. However, the recent identification of novel AstV in humans^{33–35,69} by highly sensitive methods highlights the necessity to analyze the prevalence of these novel viruses to determine their actual impact in public health, especially because they were found to be genetically related to animal viruses and some were isolated from patients with more severe diseases, such as encephalitis. Limited studies suggest that these viruses, similarly to the canonical HAstV, may be distributed worldwide in the human population.^{32,69} Given their genetic relationship with animal viruses and the potential for interspecies transmission, it would be possible that wild animals may become part of the epidemiologic equation.

Morbidity and Mortality

Although the gastroenteritis caused by HAstV is usually a mild, self-limiting illness that does not require hospitalization, more

severe gastroenterologic disease that may result in death has also been reported.¹¹² Astrovirus infection has been associated with intestinal diseases other than gastroenteritis, such as celiac disease¹²⁷ and intussusception,^{4,63} and it was found as the only pathogen in the CNS of a child with encephalitis.¹¹⁵ In a population of Mayan infants, astrovirus was the most common enteric pathogen identified in stool samples collected during a prospective study of oral poliovirus immunogenicity.⁸⁷ In 61% of the infants, astrovirus was detected by EIA in at least one stool sample over the 18-week period each infant was followed. Of 305 diarrheal episodes reported at study visits, 26% were associated with astrovirus. The enzyme immuno assay (EIA) results were confirmed by reverse transcription-polymerase chain reaction (RT-PCR) in a subset of EIA-positive and -negative samples. The reason for the high prevalence of astrovirus infection and the low rate of rotavirus infection (4%) in this semiclosed community is not known, but it may be related to temperature, rainfall, humidity, or other environmental factors.

HAstV were shown to be an important cause of outbreaks of diarrhea in the childcare setting. Children up to 36 months of age attending childcare centers were at greatest risk of developing diarrhea.⁹⁹ An investigation of eight outbreaks of astrovirus diarrhea in six childcare centers showed that 20% of the children with diarrhea shed astrovirus.⁹⁸

Origin and Transmission

Epidemiologic data indicate that contaminated food is the main source for HAstV infection. HAstV has been found in bivalve mollusks, indicating that seafood may contribute to gastroenteritis caused by HAstV.¹³⁹ HAstV has also been detected in water from different origins, including drinking water, rivers, dams, wastewater, and effluents from water treatment plants.^{81,90,108,114} Sequence analysis of HAstV strains recovered from water and clinical samples from hospitalized patients showed that virus strains from both origins were identical,¹⁰⁸ confirming that water supplies are an important source of HAstV contamination. In ground water, the infectivity of astrovirus can be maintained for months; besides, it is partially resistant to chlorination,³¹ which is widely used for wastewater treatment in many countries.

The identification of astroviruses in the human population—different from canonical HAstV but genetically related to AstV isolated from rats,²⁴ minks,⁶⁹ marine mammals,¹¹⁷ and pigs⁸⁵—suggested that wild mammals might act as reservoirs for human AstV, and that interspecies transmission occurs. The identification of a recombinant virus containing sequences derived from HAstV-4 and CslAstV in sea lions supports this hypothesis.¹¹⁷ A high diversity of AstV has been found in mammals, such as bats¹⁵² and pigs,⁸⁵ suggesting that the emergence of novel viruses in humans is possible.

Seroprevalence

Antibodies to canonical HAstV tend to be acquired in early childhood, which is consistent with the age at which children are primarily infected. An early survey of 87 children less than 10 years of age in the Oxford region of the United Kingdom revealed that antibody prevalence rises rapidly from 7% in 6- to 12-month-old infants to 70% by school age.⁷⁷ This study was focused on detecting HAstV antibodies by immunofluorescence of astrovirus-infected cells; therefore, the prevalence of antibodies to astrovirus in this population could be underestimated.

The presence of high titers of antibodies to HAsV, particularly to HAsV-1 capsid protein,²⁷ in gammaglobulin pools from the United States indicates that HAsV infection with this serotype is very common. As expected, based on the most frequent HAsV serotype found to cause infection in different studies, one study of seroprevalence among children treated at a hospital in the United Kingdom found rates of 86% for serotype 1, 1% for serotype 2, 8% for serotype 3, and 6% for serotype 4.¹¹¹ In an age-stratified sample from The Netherlands, seroprevalence of neutralizing antibodies was again higher for serotype 1 (91%), but it was different for the other serotypes.⁷⁵ Studies to determine the seroprevalence of antibodies to the recently identified human isolates—such as HAsV-HMO, -MLB, and -VA1—are still pending, although limited studies with the HAsV-MLB-like virus strain indicate that they are also widely distributed in the human population.^{34,69}

CLINICAL FEATURES

Characteristics of Human Illness

Gastroenteritis caused by astrovirus infection primarily affects young children throughout the world. Table 21.1 summarizes the clinical features associated with this disease; however, these features can vary depending on the population studied. For instance, 12.4% of outpatients under 36 months of age infected with HAsV in Argentina got diarrhea, 41.6% had fever, and 16.6% of the patients required hospitalization⁴⁶; in Egypt, diarrhea caused by HAsV in children under the age of 3 years was similar to that caused by rotavirus, and severe dehydration was present in 17% of these patients.¹⁰⁹ Complications such as dehydration can develop in patients with underlying

gastrointestinal disease, poor nutritional status, and mixed infection.²⁶

Adult human volunteer studies established the incubation period to be 3 to 4 days and the highest viral shedding at day 6, which appeared to be proportional to the severity of the illness; seroconversion was confirmed at day 28.⁹⁷ Development of disease in these patients was limited and dependent on the size of the inoculum. A shorter incubation period of 24 to 36 hours was calculated from the secondary spread characteristics during an outbreak of gastroenteritis in a Japanese kindergarten.⁷⁴ In general, astrovirus diarrhea is milder than that caused by rotavirus and does not lead to significant dehydration or hospitalization.¹⁴¹ Persistent gastroenteritis caused by astrovirus has been associated with strains belonging to serotype 3.²¹ Deaths associated with gastrointestinal astrovirus infection are extremely rare but have been reported.¹²⁶

Additional gastrointestinal diseases associated with canonical HAsV include intussusception^{4,63} and necrotizing enterocolitis,^{5,6} while the recently described HAsV-VA1 was found in celiac disease.¹²⁷ HAsV was found in 3 out of 6 pediatric patients (between 4 and 7 months) with ileocolic intussusception; in two, HAsV was the only pathogen found and one died.⁴ In premature children, HAsV was the most frequently associated viral pathogen with necrotizing enterocolitis.⁶

HAsV has been found to be the cause of chronic diarrhea among immunocompromised patients, children, and adults, and of outbreaks in pediatric patients undergoing bone marrow transplantation²⁷ and pediatric primary immunodeficiency units.⁴⁰ Among gastrointestinal viruses, HAsV have been found more frequently in patients with a number of immune diseases, such as human immunodeficiency (HIV positives), combined immunodeficiency, congenital T-cell immunodeficiency, chronic lymphocytic leukemia, Waldenström's macroglobulinemia, and immunodeficiency polyendocrinopathy.^{15,40,50,149} Patients treated with fludarabine, which is known to deplete CD4+ T cells, developed persistent diarrhea caused by HAsV.¹⁵

Astroviruses have been identified in feces of children with nonpoliovirus flaccid paralysis⁶⁹ and in frontal cortex biopsy of a patient with X-linked agammaglobulinemia who developed encephalitis.¹¹⁵

Clinical Features in Avian Species

Intestinal and extraintestinal illness has been noted in avian species infected with astroviruses. Avian nephritis virus (ANV) infects chickens, and the viral antigen can be found in different organs (e.g., liver, spleen, pancreas, kidney, jejunum, and ileum) of this animal. This virus has been associated with growth retardation and acute interstitial nephritis.⁶² Antigenically ANV-unrelated astrovirus (confirmed to be different by sequence analysis of a specific region of the nonstructural polyprotein) isolated from chickens were found in the small intestine, but rarely in other organs; these viruses were associated with mild diarrhea.¹⁰ In ducks, astrovirus infection is associated with fatal hepatitis, with mortality rates of up to 50%.⁴⁷ Subcutaneous injection of a 20% (w/v) suspension of astrovirus-infected livers into 2- to 3-day-old ducklings recapitulated the hepatitis with all of the histologic features of the original animals and caused death within 2 to 4 days in 25% of the ducklings. Serial passage of this agent in ducks resulted in mortality rates of 25% to 55%. However, asymptomatic DAsV infections seem to be present at high frequency since

TABLE 21.1 Clinical Symptoms of Human Astrovirus Infection

Diarrhea	72%–100%
Duration of diarrhea (days, average)	2–3
Maximum number of stools/24 h	4
Bloody diarrhea	0%
Abdominal pain	50%
Vomiting	20%–70%
Duration of vomiting (days, average)	1
Maximum number of vomiting episodes/24 h	1
Fever	20%–25%
Maximum fever (Celsius)	37.9
Dehydration to some degree	24%–30%
Severe dehydration	0%–5%
Hospitalization	6%
Duration of hospitalization (days, average)	6
Severity score ^a (1–20) (average)	5
Otitis	13%
Bronchiolitis	33%
Admission diagnosis of gastroenteritis	18.7%–48%

^aTwenty point scoring system (Ruuska T, Vesikari T. Rotavirus disease in Finnish children: use of numerical scores for clinical severity of diarrhoeal episodes. *Scand J Infect Dis*. 1990;22:259–267.).

a significant seroprevalence on healthy animals can be found; a high seroprevalence to DAsV was also found in flocks that present a very low mortality rate.¹³⁷ Turkey astrovirus has been associated with diarrhea and the high mortality disease poult enteritis mortality syndrome (PEMS). TAsV was isolated from the thymus of an infected animal with PEMS,⁷³ but it could be detected in different tissues (e.g., bursa, thymus, spleen, kidney, pancreas, and skeletal muscle).¹⁰⁶ The small intestine, however, seems to be the main tissue where virus replication occurs.¹¹ Asymptomatic infections have been also found in turkeys as well as in chickens infected with AsV.¹³⁷

DIAGNOSIS

Electron Microscopy

Astroviruses have been detected by direct EM examination of negative-stained fecal specimens. The sensitivity of this methodology has been estimated to be 10^6 to 10^7 virus particles per gram of stool. Usually, patients with diarrhea caused by astrovirus shed large numbers of viral particles (equivalent to approximately 10^{10} or 10^{11} of virus genomes per gram of feces).⁵⁵ However, in those patients who may be excreting fewer viral particles, usage of antiviral antibodies for immunoelectron microscopy facilitates identification of the virus.

Enzyme Immunoassays

Herrmann et al. developed an EIA that relies on a group-reactive monoclonal antibody (8E7) that maps to the conserved domain of the capsid protein of HAsV serotypes 1 to 8 (amino acid residues 71 to 260) to capture viral antigen, and a polyclonal antiserum as the detector antibody.⁶⁰ This EIA had a comparable sensitivity (91%) and specificity (98%) to immune EM. EIA has been useful for rapid detection of astrovirus antigen in studies in which a large number of human samples have been assayed. However, antibodies developed by Herrmann do not recognize the recently described novel HAsV strains.

The high antigenic divergence of avian viruses has not allowed the obtention of antibodies to common epitopes to be used in immunoassays to detect all AsV that infect flocks; the DAsV capsid carboxy-terminal region has been successfully used to detect prevalence of antibodies to this virus in ducks.¹⁴³

Molecular Techniques

As more information regarding the sequence of astrovirus genomes became available, detection techniques that employ molecular probes and RT-PCR were developed. At present, the complete genome sequence of several human and animal AsV strains, as well as the ORF2 sequences from a high number of isolates, have been determined. The high sequence variability that exists among these viruses does not allow the use of universal primers for all members of the *Astroviridae* family. However, based on these sequences, oligonucleotides from selected regions of the genome have been used as primers to diagnose closely related viruses by RT-PCR and sequencing of the amplicon. Particularly, primers derived from different regions along the genome have been successfully used for RT-PCR to detect typical HAsV and animal viruses. The sensitivity of this methodology increased when it was coupled to a cell-culture system in clinical and environmental water samples.⁴⁹ Given

that different pathogens are associated with enteric infections in humans and animals, methods based in RT-PCR have been developed recently for diagnosis of multiple human or animal viruses, including astroviruses, in a single tube.^{14,118,124,151}

Diagnosis by RT-PCR has also been used to detect the presence of astrovirus in animals; however, in the case of avian astroviruses, as mentioned, common oligonucleotides cannot be used due to the high genome diversity, which is even higher than among mammastroviruses. In spite of this, quantitative RT-PCR assays for ANV and CAsV, able to detect 180 and 105 RNA copies, respectively, have been used to specifically demonstrate the presence of these viruses in the gut and kidney of field and experimental infected animals.¹²⁹ Sensitivity for ANV detection increased (detecting up to 18 RNA copies) when oligonucleotides that amplify the 3'-UTR conserved region were used.¹³⁶

Metagenomic analysis has revealed the existence of novel astroviruses in samples from patients with diseases that had not been previously associated with these viruses,^{69,115} contributing to changing the virologist community's view of their behavior and relevance. This powerful technology can help to identify emerging astroviruses, as well as many other novel pathogens, and will provide the basis to design biological reagents for specific diagnosis.

Oligonucleotide microarrays have also been used as a powerful technology to identify previously unknown viruses belonging to different families. This methodology has been evaluated to detect and type HAsV using viral cDNA or RNA from reference strains adapted to cultured cells or wild-type strains from feces.²⁰ More studies are needed to determine the usefulness and sensitivity of this methodology with clinical samples.

PREVENTION AND CONTROL

Gastroenteritis caused by astrovirus is generally a mild, self-limiting illness that can disrupt an individual's activities for a few days but does not require specific therapy. In the young child or adult patient who becomes dehydrated, oral or intravenous fluid resuscitation may be necessary. Intravenous immunoglobulin may be a useful adjunct in severely immunodeficient patients who fail to respond to conservative measures,¹⁵ but larger studies are needed to determine efficacy and establish indications. Of note, immunoglobulin treatment has been suggested as a possible cause of encephalitis in an immunodeficient patient,¹¹⁵ although this was not confirmed.

Interruption of transmission is the key factor in preventing astrovirus infection. This is especially important in hospitals and other institutions, daycare centers, and families, where person-to-person transmission is likely to occur. Astrovirus is resistant to a number of treatments, including normal disinfectants,^{80,121} and it can survive in water after chlorination.^{1,81} Therefore, universal hygienic procedures must be enforced in these settings. No vaccines have been developed for astrovirus infections in any host animal; however, inoculation of the recombinant, baculovirus-expressed capsid protein to hens partially protected the offspring for the presence of gut lesions and weight depression after virus challenge.¹²³ Thus, this kind of antigen eventually could be useful in evaluating vaccine candidates in other animal species, including humans.

PERSPECTIVES

The perception of the relevance of AstV in public health is changing given the discovery in recent years of novel viruses isolated from humans that show genetic similarities with animal strains, some of which have been associated with diseases other than gastroenteritis. Further characterization of HAsTV genetically related to animal strains will help to better understand the public health importance of astroviruses. The available evidence indicates that interspecies transmission might be common in astroviruses. Epidemiologic studies designed to search for AstV in nongastrointestinal diseases, such as those related to the CNS, will be useful in understanding the spectrum of pathology these viruses may be associated with, and could change the current knowledge we have about the epidemiology and pathology of astrovirus-associated disease. Although animal models have been established for avian viruses, models for mammalian viruses are required to study the determinants of protective immunity in these viruses and the pathogenesis of the diseases they cause. The structural analysis of AstV proteins that has already started with viral protease, and spike protein should continue to help in the understanding of the molecular determinants of infection as well as the role specific viral proteins play in the virus replication cycle. So far, neither cellular receptors nor the virus capsid protein domains involved in virus entry and cell egress have been identified for AstV. It is expected that further structural characterization of viral capsid proteins will allow us to undertake new approaches targeted to understand these processes, and also probably to control infection. Significant gaps exist in our understanding of astrovirus genome replication, especially since it occurs in the absence of a viral encoded RNA-helicase, a peculiar feature of AstV; therefore, the identification of viral and cellular proteins that participate in this process will be useful in elucidating its mechanism. The cell response to HAsTV infection has proven to be partially beneficial for virus cell entry and egress; however, the cell factors and mechanisms involved in these processes are only beginning to be characterized. Further studies are required to advance our understanding of these stages of the virus lifecycle. Although infectious clones for HAsTV and ANV have been available for some time, reverse genetics in AstV has been poorly exploited. The systems for reverse genetics should be improved and used to identify the virus molecular determinants involved in the virus replication cycle.

ACKNOWLEDGMENTS

We apologize to our colleagues whose work has not been cited due to space constraints. We thank Dr. K. Dryden and Dr. Y. J. Tao for providing unpublished data. Our laboratory acknowledges the financial support from DGAPA–National University of Mexico (UNAM) and the National Council for Science and Technology (CONACYT).

Perspectives

The togaviruses are simple enveloped plus-strand RNA viruses that are spherical in appearance and contribute significantly to human disease. Although they were originally classified together with several groups of viruses that are transmitted predominantly by insects, more recent analyses have categorized them into a distinct family with two genera: *Alphavirus* and the *Rubivirus*.^{167,208} The *Alphavirus* genus is by far the larger of the two, with about 30 recognized members, whereas the *Rubivirus* genus is composed of a single member, rubella virus. Virus classification into each group is determined by genome organization and nucleotide homologies. The alphaviruses are responsible for a variety of human and animal diseases, involving encephalitis, arthritis, fever, and rash, and are transmitted primarily by arthropod vectors. Viruses such as Chikungunya (CHIKV) and Venezuelan equine encephalitis virus (VEEV) have been responsible for recent human outbreaks and have raised awareness of the

significance and potential threat of alphaviruses to human health. Rubella virus is a common childhood illness for which an effective vaccine is available. However, in the absence of immunity, the virus can induce severe congenital defects in the fetuses of infected women.

Sindbis virus (SINV), the type-member of the alphavirus genus, has been studied extensively, in large part due to its facile growth in cell culture and its ability to cause mild or inapparent illness in humans. The virus has an 11.7-kb RNA genome that is capped at its 5' end and contains a poly A tract at its 3' terminus.²⁶⁵ Virions have a spherical icosahedral arrangement of proteins that has facilitated their structural analysis. The detailed knowledge of the viral life cycle, which is the focus of this chapter, has been exploited for the development of alphavirus gene expression vectors. Many members of this virus group have been studied for their role in pathogenesis. Rubella virus, as expected from its classification, shares a number of properties with the alphaviruses, yet has several important distinctions that are highlighted throughout the chapter.

CLASSIFICATION OF VIRUSES WITHIN THE TOGAVIRIDAE FAMILY

Viruses transmitted by arthropods have been referred to as arboviruses.²⁰⁸ It was originally noted that many arboviruses had a similar morphologic structure, as observed by electron microscopy, that resembled a Roman cloak (in Latin, *toga*), hence the name togaviruses. Originally, the family *Togaviridae* consisted of group A (alphaviruses) and group B (flaviviruses); however, the genera *Rubivirus* and *Pestivirus* were later added based on their similar physical properties but despite their lack of arthropod transmission. With the development of sequencing, it became apparent that the original joint classification for these viruses was in error. The *togaviruses* have nonstructural or replication proteins encoded at the 5' end of their genome RNA, whereas the 3' end encodes the proteins that comprise the virus particle, or virion. In the togaviruses, these structural proteins are translated from a subgenomic messenger RNA (mRNA) that derives from, and is co-terminal with, the 3' end of the genome.^{219,265}

The larger of the two genera within togaviruses, the *Alphaviruses*, has been classified into seven antigenically related complexes.²⁰⁹ Most phylogenetic analyses support this classification, but several recent additions add complexity to the organization. The alphaviruses have a worldwide geographic distribution, including the continent of Antarctica. The alphaviruses have classically been described as either Old World or New World viruses, depending on their distribution, and it is

likely that several transoceanic exchanges have occurred.²⁰⁹ Most alphaviruses are transmitted by arthropod vectors that probably control their geographic dispersal. However, the recent identification of the salmonid viruses, salmon pancreas disease virus, and sleeping disease virus (infecting rainbow trout), present examples of alphaviruses for which arthropod transmission is unlikely.^{293,309} These salmonid viruses appear to have diverged from the Old World–New World lineages early in alphavirus evolution, with no present-day close relatives. Another identified alphavirus, southern elephant seal virus, has been isolated from the louse *Lepidophthirus macrorhini*.¹⁵¹ This isolation demonstrates not only that alphaviruses are transmitted by lice, but that they can also infect marine mammals, and a recent report suggests a marine origin for the alphaviruses.⁵¹ Given this wide host range, it seems probable that amphibian- and reptile-specific alphaviruses also await future identification.

Although the alphaviruses and rubella virus have been classified within the same family, the evolutionary relationship between them is obscure.⁵⁴ They have a similar genome organization, and their virions share physical similarities, yet their replication and assembly strategies are sufficiently diverse to question whether they arose from a direct ancestor.

VIRION STRUCTURE

Structure of Mature Virion

The structure of the alphavirus virion has been extensively studied, and numerous high-resolution structural studies now provide a near-atomic view of the virion. Although a variety of biophysical methods were used to elaborate the alphavirus structure, work that has advanced the field the most has come from cryo-electron microscopy (cryo-EM) and image reconstruction techniques.^{93,94,287,288} The virion is 70 nm in diameter, with a molecular mass of 52×10^6 D and a density of 1.22 g per cc. It is composed of repeating units of the E1 and E2 transmembrane

glycoproteins, the capsid or nucleocapsid protein (C), a host-derived lipid bilayer, and a single molecule of genome RNA. The protein components of the virion are arranged as a T = 4 icosahedral lattice, with 240 copies of each subunit.^{27,198,201} These subunits interact with one another to form a rigid structure across the membrane in a one-to-one relationship between glycoprotein E2 and the capsid protein. Smaller amounts of another membrane-associated protein, 6K, are also found in the virus particle.^{64,162} More recently it has been discovered that another small protein, the TransFrame (TF) protein, is found in substoichiometric amounts in the virion.⁴⁷ The lipid bilayer is derived from the host plasma membrane and is enriched in cholesterol and sphingolipid, molecules that are required for entry and budding.¹¹⁴ Inside the bilayer, the C surrounds the genome RNA and forms an icosahedral shell. Thus, the alphaviruses are composed of multiple organized shells of molecules that effectively protect and deliver the viral RNA to susceptible host cells.

Cryo-EM has been used extensively to study the structure of alphaviruses, including SINV,¹⁹⁸ Semliki Forest virus (SFV),²⁸³ Ross River virus (RRV),²⁷ VEEV,^{197,315} Western equine encephalitis virus (WEEV),²⁴⁷ Aura virus,³¹⁶ CHIKV,^{298a} and Barmah Forest virus (BFV).¹²² The most recent studies with VEEV, BFV, and SINV are the most advanced, with a resolution between 4.4 and 7.0 Å reported for these viruses.^{122,315} The surface view of the virion, seen in Figure 22.1 for SINV, reveals a spherical particle with spike protrusions rising 100 Å from the surface. The icosahedral nature of the particle results in an ordered distribution of the petal-like spikes. The asymmetric unit, which is shaded in green in Figure 22.1A, contains four E1–E2 heterodimers. Each spike consists of three heterodimers of E1 and E2 glycoproteins. A total of 80 spikes reside on icosahedral threefold (solid black triangle in Fig. 22.1A) and quasi-threefold axes (open white triangles in Fig. 22.1A). Earlier biochemical studies established the nature of the heterodimer, and this relationship has been confirmed

FIGURE 22.1. Structure of alphaviruses determined using cryo-EM. **A:** Surface-shaded view of Sindbis virus as determined by cryo-electron microscopy (cryo-EM) at 7.0 Å. The trimeric petal-shaped spikes are visible, with solid triangles representing the threefold axes, and white triangles representing quasi-threefold axes. One of the asymmetric units is highlighted by green shading. **B:** The same view as shown in A but with the front half of the reconstructed structure removed. The outer layer containing spikes is shown in blue, whereas the underlying skirt density is in magenta. Crossing the lipid bilayer (cyan) reveals the ordered capsid protein (green; residues 114–264), a disordered region containing a mix of protein and RNA (yellow), and a region containing the remainder of the RNA genome (red). The transmembrane densities of E1 and E2 are seen spanning the outer and inner leaflets of the lipid bilayer (cyan). (Reproduced from Tang J, Jose J, Chipman P, et al. Molecular links between the E2 envelope glycoprotein and nucleocapsid core in Sindbis virus. *J Mol Biol* 2011;414:442–459; copyright 2011, with permission from Elsevier.)

by cryo-EM reconstructions^{218,321} and by x-ray crystallography.^{145,289} Although the protein lattice occupies a substantial surface area, small openings are present in the virion that reveal the underlying lipid bilayer. These openings are most pronounced at the twofold axes, but can also be found at the fivefold axes and around the base of each spike.

The transmembrane components of the two glycoproteins are clearly seen in the cryo-EM reconstructions (Fig. 22.1B). The shape of density suggests that each transmembrane segment traverses the bilayer as a helix, although the E1 transmembrane domain is better represented by two alpha helices separated by a two amino acid kink.³¹⁵ For SINV the E1 glycoprotein has five amino acid residues that penetrate across to the inner side of the membrane (cdE1), whereas E2 has 33 amino acids (cdE2) that interact with the nucleocapsid core.^{14,148,153,271} This interaction is observed in cryo-EM reconstructions and demonstrates that each E2 molecule makes specific contacts with each capsid protein. The nucleocapsid core has a $T = 4$ arrangement of capsid protein, with the C-terminal protease domain forming pentameric and hexameric projections that appear as capsomeres on the surface of nucleocapsid cores (shown in green in Fig. 22.1B). The genome RNA does not appear to assume regular symmetry within the nucleocapsid core and is not ordered in the reconstructions (red in Fig. 22.1B).

Structure of Immature Virion

The structure of the immature virus containing an uncleaved precursor to E2, called PE2 or p62, has also been solved using cryo-EM.^{46,200} Mutant versions of both SINV and SFV were used for independent structure determinations resulting in similar structures. The extra density corresponding to the small protein E3 was found predominantly between the petals of the spike resulting in a dual-lobed petal. At a resolution of 25 Å, no apparent differences were found in the skirt or other regions of the spike and suggest that following cleavage of PE2 and release of E3, no significant conformational changes occur in the virus structure. The immature form of the virus that contains PE2 has been proposed to stabilize the fusion protein as it transits the mildly acidic environment of the Golgi.^{155,157,291}

Structural Proteins of the Virion

The proteins that comprise the alphavirus virion are synthesized as a polyprotein from a subgenomic RNA and are shown in Figure 22.2. The structures of the three major virion proteins have been determined by x-ray crystallography to high resolution. The capsid protein functions to encapsidate the genome RNA and forms a $T = 4$ icosahedron prior to release from the cell. The 264 amino acid capsid protein of SINV was crystallized, although the N-terminal 105 residues have been absent in all of the final structures.²⁹ It was suggested that the highly basic N-terminal domain was susceptible to proteases and degraded during crystal growth. A similar observation was made for the SFV capsid protein.²⁸ The C-terminal residues 114 to 264 of the SINV capsid protein form a chymotrypsin-like fold with the ultimate residue tryptophan 264 bound in the active-site protease pocket. The fold contains two Greek key β -barrel domains that bring the catalytic triad of Ser215, His141, and Asp163 into juxtaposition for activity.⁸⁶ This structure substantiated biochemical and genetic data that proposed that the capsid protein had an autocatalytic serine protease activity.^{10,85,168} The atomic structure of the capsid protein was used to generate a “pseudoatomic” resolution structure of the alphavirus nucleocapsid core (Figure 22.3) by fitting its coordinates into the cryo-EM density.^{27,179,228} This was accomplished and it was suggested that the missing residues of the N-terminus would point inward from the core surface and interact with the negatively charged viral RNA. The recent 4.4 Å cryo-EM structure of VEEV provides support for the earlier fitted structures, but the N-terminal basic domain residues (1–110). Remains obscure as ordered density within the nucleocapsid core has not been observed.³¹⁵

The E1 protein functions as a class II fusion machine to promote the joining of viral and cellular membranes under conditions of low pH. The structure of the E1 molecule from SFV was solved using x-ray crystallography.¹³⁸ The starting material for crystallization was the SFV spike cleaved with subtilisin, which released the ectodomains of the E1 and E2 glycoproteins.³⁰⁷ Unfortunately, the crystals contained only the E1 polypeptide, and it was assumed that E2 was proteolyzed.

FIGURE 22.2. A schematic of the Sindbis virus structural polyprotein. The individual proteins are color coded, with protease cleavage sites indicated by an arrow. N-linked glycosylation sites are shown by green arrowheads. The amino acids that comprise the transmembrane and cytoplasmic domains of both E1 and E2 are shown. Asterisks indicate residues of cdE2 that interact with the capsid protein. The TransFrame (TF) protein is identified by the bent arrow followed by the dotted line crossing E1.

FIGURE 22.3. Pseudoatomic representation of the Sindbis virus structural proteins based on the 7.0 Å cryo-electron microscopy (cryo-EM) reconstruction. **A:** The structure of E1 and E2 of Sindbis virus. E1 is shown in red. The A and C domains of E2 are shown in two colors, with one representing the structure from the crystal structure (cyan) and the other obtained by fitting the crystal structure into the cryo-EM map (green). The B domain of E2 (blue) is a homology-modeled structure derived from the Chikungunya crystal structure. The arrow points to the E1 fusion peptide (yellow). **B:** Same as in **A** but fitted into the cryo-EM density (grey mesh). **C:** Cross-section of the fitted cryo-EM structure showing the transmembrane helices of E1 (red) and E2 (green) and the underlying N-terminal protease domain of the capsid protein (residues 114–264). Below capsid residue 114 (blue ball), the remaining N-terminal residues of the capsid are not identified but must interact with the underlying genome RNA. Additional EM density is shown in gray. **D:** Interactions between the capsid protein and the cdE2. The residues that comprise cdE2 (amino acids 391–423) were modeled according to the cryo-EM density and are shown as they interact with the hydrophobic pocket of the capsid protein. Residues of the capsid that have been shown as important in this interaction—F166, Y180, and W247—are highlighted. (Reproduced from Tang J, Jose J, Chipman P, et al. Molecular links between the E2 envelope glycoprotein and nucleocapsid core in Sindbis virus. *J Mol Biol* 2011;414:442–459; copyright 2011, with permission from Elsevier.)

The structure of the E1 ectodomain (residues 1–383) is shown in Figure 22.3 and contains three β -barrel domains. Domain I, the so-called central domain, links domains II and III. The extended domain II contains at its distal end the fusion peptide, a short loop of hydrophobic amino acids that promotes insertion of the protein into the target membrane. Domain III has an immunoglobulin (Ig)-like fold and connects at its C-terminus with the transmembrane domain of the protein.

The structure of E1 is remarkably similar to that of the flavivirus E protein.^{217,269} Unlike the alphaviruses, the flavivirus E protein functions both in receptor attachment and in membrane fusion. In the alphaviruses, these two activities are carried

out by proteins E2 and E1, respectively. In the flaviviruses, the E protein is oriented roughly parallel to the lipid membrane, and it was anticipated that E1 might assume a similar orientation in the alphavirus virion.¹²⁴ This was essentially verified once the E1 atomic structure was fitted into the cryo-EM density. This fitting was accomplished for both SFV and SINV, and most recently for CHIKV.^{138,145,207,289} Furthermore, for SINV, the two sites of E1 glycosylation were mapped onto the cryo-EM structure, and these sites at Asn139 and Asn245 were used as positional markers to fix the position of E1 in the virion.²⁰⁷ E1 lies at an angle of ~50 degrees relative to the surface of the membrane (Figure 22.3B), and it forms an icosahedral lattice

comprising the region that has been referred to as the skirt.^{138,207} The crystallographic E1 dimer, which is a back-to-back dimer as opposed to a face-to-face dimer seen in the flaviviruses, is essentially preserved in the arrangement of E1 in the virion. The interface residues that make contact in the crystallographic dimer are presumably those that are important for forming the icosahedral lattice in the virion.

Although E1 comprises the skirt region of the alphavirus surface, the majority of the protruding spike is comprised of the E2 molecule. E2 constitutes the petals that make up the spike, and covers the distal end of the E1 molecule that points outward. E2 serves to engage cell surface receptor molecules required for entry of the virion into the cell. The crystal structure of E2 together with both E1 and E3 for CHIKV was solved and reveals a three-immunoglobulin domain protein.²⁸⁹ Domain B is located at the outermost point of the spike and contains the residues that have been implicated in receptor binding and as well as those involved in binding neutralizing antibodies. Domain B exhibits mobility in the context of the spike and was absent from the intact SINV E1–E2 trimer structure done at low pH.¹⁴⁵ At the other end of the protein, located closest to the viral membrane, is the C-terminal domain C. The N-terminal domain A (residues 1–132 in SINV) is the central bridge of E2, and connections are made to the B domain by β -ribbon connectors. The β -ribbon connector is flanked by a pair of well-conserved histidine residues that might function as an acid switch to release the connector and B domain under acidic conditions. Although E3 does not directly contact E1, its contact with the β -ribbon connector holds it in place to prevent movement of the B domain while the virus is in the process of egress from the cell in an immature state. The furin cleavage of the p62 to release E3, therefore, releases the clamp

holding the B domain and activating the complex for pH-triggered fusion. E1 and E2 have extensive contacts with each other, promoting the spike architecture (Fig. 22.3).

In addition to the three major structural proteins identified by cryo-EM in the virion, two small transmembrane proteins are present in sub-stoichiometric amounts and can be identified using purified virus and mass spectrometry. The existence of the 6K protein in the virion has been well established, but more recently the TF protein (~8 kD) has also been found within SFV particles.⁴⁷ Given the low abundance and presumably random distribution of these small transmembrane proteins, they have not been detected using high-resolution cryo-EM, and their membrane architecture has to date prevented x-ray crystal structures. Whether the TF and 6K proteins exist as oligomers is also unknown.

GENOME STRUCTURE AND ORGANIZATION

The togavirus genome resides on a positive-strand RNA that contains a 5' terminal 7-methylguanosine and a 3' terminus that is polyadenylated. The alphavirus genome, represented in Figure 22.4 by the type virus SINV, is approximately 11.7 kb in length, whereas rubella virus is nearly 2 kb shorter, at 9.8 kb.^{40,265} The genomes segregate their replication and virion protein coding regions into two segments, with the replication region mapping to the 5' two-thirds and the structural region mapping to the 3' one-third. Limited nucleotide homology exists between genomes in the two genera, although there are several sequences in both translated and nontranslated regions that do have homology; however, most evidence suggests that their replication and assembly strategies are quite different.⁴⁰

Alphavirus (Sindbis virus)

Rubivirus (rubella virus)

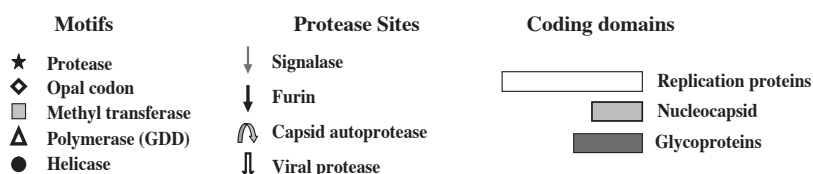

FIGURE 22.4. The genomes of Sindbis virus and rubella virus. Nontranslated regions are shown by the solid line and translated regions are shown in boxes. Open boxes indicate replication proteins and shaded boxes represent structural or virion proteins. Motifs and cleavage sites are indicated according to the scheme. The subgenomic mRNAs are not shown to scale with the genomic RNAs.

The nonstructural or replication proteins are translated from the genome RNA, whereas the structural or virion proteins are translated from a subgenomic mRNA.^{191,251} In SINV, the 5′ nontranslated region (NTR) is 59 nucleotides, about average for the alphaviruses, whereas the 3′ NTR is also close to the average in length at 322 nucleotides.

Using comparative genome analyses and functional genetic studies of defective interfering particles and viruses, four conserved regions (conserved sequence element [CSE]) of the alphavirus genome were identified as *cis*-acting elements important for replication.^{184,185–186} Two conserved regions are found near the 5′ end of the genome, one is found in the junction region between nonstructural and structural genes, and one is found at the 3′ end immediately preceding the poly (A). Three presumably similar functioning CSEs can also be found in the rubella genome.⁴⁰ In the alphaviruses, each CSE has been shown to interact in a host-dependent manner, suggesting that host factors may play a role in their function.^{44,97,98,123,187,188} It has been shown that a U-rich region in the 3′ NTR of SINV contains elements responsible for viral RNA stability and that the cellular HuR protein binds this region, thus decreasing the rate of cell-mediated decay of the genome RNA.²⁶⁰ In addition, studies have shown that host proteins bind to the 3′ end of the minus-strand RNA of SINV, and in one case the protein was identified as the mosquito homolog to the La protein.^{193,194–195}

ALPHAVIRUS REPLICATION

Mechanism of Attachment and Receptors

Alphaviruses display an extremely broad host range, both in terms of susceptible animal species and in terms of cells in culture. This broad host range has prompted speculation as to the nature of the receptor, with two hypotheses proposed to explain this phenomenon.²⁶⁶ In the first, the virus E2 glycoprotein contains multiple receptor-binding sites so that distinct cellular receptors can bind the viral surface protein. The second hypothesis proposes that the virus uses a ubiquitous receptor that is highly conserved across species, including both mammals and mosquitoes. Data exist to support each model, and it is likely that a combination of the two is the true strategy for alphavirus attachment to the cell.

The variety of molecules that have been implicated in SINV argues for multiple distinct receptor-binding sites on E2.²⁶⁶ The use of the laminin receptor with its high conservation across species suggests that it might serve as a receptor in multiple cell types and multiple host species.²⁹⁵ However, the picture remains obscure for SINV because laminin receptor functions in baby hamster kidney cells but not in chicken embryo fibroblasts, where a 63-kD protein has been implicated.²⁹⁶ In mouse neuroblastoma cells, proteins of 74 and 110 kD have been reported as possible SINV cellular receptors.²⁷⁸ DC-SIGN and L-SIGN, C-type lectins that bind mannose-enriched carbohydrates, have also been implicated as receptors of alphaviruses that have been produced in mosquito cells.¹¹⁸ Very recent studies using a genome-wide RNA interference (RNAi) screen in *Drosophila* cells identified the natural resistance-associated macrophage protein (NRAMP) as a cellular receptor functioning to permit SINV infection.²²⁶ Likewise, NRAMP2, the vertebrate homolog, allowed for SINV, but not RRV, entry into mammalian cells. This new approach and

finding raises the possibility that a family of related conserved multipass membrane proteins may serve as receptors for other alphaviruses.

Natural isolates of EEEV utilize cell surface heparan sulfate as an attachment receptor.⁶⁵ This use of heparan sulfate may direct tropism of EEEV and promote enhanced neurovirulence. In contrast, passage of several other alphaviruses in culture leads to the accumulation of adaptive mutations, some of which introduce basic amino acids in their E2 glycoprotein.^{18,20,21,119} This increase in positively charged amino acids in E2 leads to high efficiency attachment to cells through heparan sulfate molecules. The importance of this interaction was demonstrated genetically by the generation of a Chinese hamster ovary cell line using retroviral insertional mutagenesis that was deficient in the expression of heparan sulfate and chondroitin sulfate.¹⁰⁸ These cells were resistant to SINV infection and defective in binding virus. The substitution of a single residue on the E2 glycoprotein of RRV was sufficient to permit heparan sulfate binding, and this attachment was mapped using cryo-EM to the distal tip of the spike.^{97,317} The binding of heparan sulfate does not result in conformational changes in the virion, nor does it enhance the fusion process.^{257,317} Therefore, it likely serves simply as a mechanism to attach the particle to the cell surface with high affinity so an efficient interaction with the entry receptor can occur. In contrast to what is observed in cell culture with SINV, infection of mice results in the development of large-plaque viral mutants with a reduced affinity for heparan sulfate and a greater viremia.²¹ However, given these diverse observations, the utilization of heparan sulfate and its role in pathogenesis among the different alphaviruses requires further investigation.

Mechanisms of Entry, Membrane Fusion, and Uncoating

Following attachment to cells and engagement with an entry receptor, alphaviruses proceed via the endocytic pathway to gain access to the cell interior (Fig. 22.5).^{38,98,166} Structural and biochemical experiments demonstrate that binding of RRV to heparan sulfate does not induce conformational changes in the virion.^{257,317} However, other receptors may induce conformational changes in the particle that might mediate entry such as the reduction of disulfide bonds to disrupt protein–protein interactions.^{1,11,199,237} Despite these suggestions that disulfide exchange may play a role in alphavirus entry, the use of thiol-blocking reagents failed to show a significant inhibition of infection.⁷⁷ However, it is clear that the attachment of SINV to cells results in the exposure of new epitopes defined by monoclonal antibodies and suggests that protein rearrangements occur following receptor engagement.^{48,172} Similar observations have been made using purified virus and treatment with heat, pH, and reducing agents.¹⁷¹ In addition, the recent observations on the role of virion and protein dynamics in the flavivirus life cycle, suggest that other structurally related viruses might employ particle dynamics to sense their environment as they search for an entry receptor.^{40a} In addition to the role of thiol exchange reactions that have been proposed to play a role in alphavirus entry, there has even been a suggestion that cell penetration may occur at the cell surface in the absence of fusion by conformational rearrangements in the envelope glycoproteins.^{1,199} However, it has been fairly well established that membrane fusion triggered by an exposure to acidic conditions

FIGURE 22.5. Life cycle of an alphavirus. The start of the life cycle is shown on the **left** with the attachment of a virion to the cellular receptor. Following fusion of the viral envelope, disassembly of the core, and release of the genome RNA, replication proteins are translated and processed (**bottom left**). These proteins enable the replication of the input genome RNA (**bottom center**), and translation of the subgenomic mRNA into structural proteins. Cytoplasmic assembly of genome RNA and capsid produces the nucleocapsid core that associates with processed glycoproteins (**right**) at the plasma membrane resulting in budding. (Scale varies.)

is the gateway for the release of genome RNA into the cytoplasm (Fig. 22.6).

Receptor-bound viruses undergo endocytosis into coated vesicles using a clathrin-dependent pathway. This pathway was demonstrated by DeTulleo and Kirchhausen³⁸ using dominant-negative mutants of dynamin to block the formation of clathrin-coated pits and prevent entry of SFV and SINV. The vesicles are subsequently acidified, providing the trigger for fusion between viral and cellular membranes. Acid-induced fusion is supported by numerous studies, but most convincingly by the use of lysosomotropic weak bases that raise the pH of endocytic vesicles and prevent entry of alphaviruses.^{77,99,310} Although it has been argued that viral RNA replication might also be affected by the acidification, pseudotyped viruses con-

taining alphavirus envelope proteins are also inhibited in entry by this treatment.^{42,100,246}

The role of the alphavirus E1 and E2 glycoproteins in the entry process has been firmly established (Figs. 22.6 and 22.7). In the presence of acidic pH, the E1–E2 heterodimer is destabilized and the two proteins dissociate.^{291,293} The dissociation of the proteins results in the exposure of the fusion peptide that is found on the distal tip of E1.^{4,74,88,138} The fusion peptide of E1 inserts into the target membrane in a cholesterol-dependent manner followed by the trimerization of E1.^{3,73,116,189,206,292} A large conformational change in E1 results in domain III and the stem-anchor region of the protein packing against domain II, resulting in the viral and target membranes being brought into close opposition (Fig. 22.6).⁷⁶ A set of E1 trimers, possibly

A and **B**: Neutral and low pH forms of the soluble E1 ectodomain lacking amino acid residues 392–438, respectively. The orientation of the protein presents the fusion loop (cd loop) toward the target membrane (**top**). **C**: This rearrangement would occur after E1 has undergone trimerization as shown here. (Modified from an image provided by Dr. Felix Rey; 76.)

resembling what has been seen in liposomes, results in membrane deformation and promotes membrane mixing.⁷⁴ Finally, a fusion pore will form as the two membranes complete the process, and the nucleocapsid core will be released into the cytoplasm (Fig. 22.7).

Rey et al.¹³⁸ recognized that the structural features of the alphavirus E1 and flavivirus E proteins were distinct from the structures of other previously identified fusion proteins such as hemagglutinin (HA) from influenza, and proposed that they represented a novel class of fusion machines. They termed these class II membrane fusion proteins and elaborated several distinguishing features that separated the two classes. Class II fusion proteins are composed predominantly of β -strands, contain an internal fusion peptide, and have a companion protein that stabilizes the structure; this companion protein forms an activated metastable structure following proteolytic processing of a precursor protein. In the alphaviruses, PE2 is proteolytically activated by cleavage to generate E3 and E2, with E2 and E1 forming a stable heterodimer.^{155,156} Mutagenesis experiments have provided insight into the fusion process and the residues that play regulatory and supporting roles in this process. As predicted, a pH-sensitive histidine residue in E1 (SFV H3) appears to regulate the low pH-dependent folding of E1 that is required for fusion.²¹⁵ Several other well-conserved histidines in E1 were evaluated and found unable to influence the activity. In addition, Kielian and colleagues¹⁵² found that a salt bridge is formed within domain II of the E1 trimer core, which appears critical for stabilizing the homotrimer fusion intermediate.

Biochemical experiments with SFV have defined the requirements and steps in the alphavirus fusion process. Kielian et al.^{116,159,206} demonstrated a strict dependence on cholesterol for fusion. This requirement has been narrowed down to the sterol β hydroxyl group in cholesterol.^{31,176,290,312} A mutant was isolated (named *srf-3* for sterol requirement in function) that was cholesterol independent and had an amino acid substitution of a proline to serine at E1 residue 226. This mutation did not affect fusion with normal membranes but significantly enhanced fusion to cholesterol-free membranes.^{24,280} In mosquito cells, the *srf-3* mutant grew better than wild-type virus.⁵ The importance of this region of E1, which lies in the ij loop,

for alphavirus fusion was further demonstrated by mutation of a conserved histidine at position 230 to alanine with the resulting virus particles being noninfectious, but capable of proceeding through E1 homotrimer formation under low pH conditions and suggesting a late step in fusion.²³ However, the exact role of cholesterol to promote fusion is not known. The structure of the postfusion form of E1 has been determined using x-ray crystallography.^{74,75,76} This was accomplished using a soluble form of the E1 ectodomain known as E1* following exposure to low pH in the presence of liposomes, and solubilization with detergents. The structure of this homotrimer reveals the movement of domain III by 37 Å toward the fusion peptide and target membrane (Fig. 22.6)⁷⁶ and is similar to changes that are induced by class I fusion protein activation.¹¹⁵ It is important to note that the addition of exogenous domain III can inhibit fusion by binding to E1 and preventing fold-back of the endogenous domain III.¹⁴⁶ This fold-back process appears to be reversible and is mediated by a series of interactions between the domain I and domain III linker region.³²⁰ A complete picture of the virion during the fusion process is not available, despite several attempts using cryo-EM to examine these steps.^{46,62,84,199}

Following the fusion of the viral and cellular membranes, the nucleocapsid core is released into the cytoplasm. The stability of that core is not known, but uncoating has been suggested to require the interaction of the core with ribosomes. This is based on several reports that suggest that ribosomal RNA competes for a site on the capsid protein and that displacement of this site results in disassembly.^{253,254,305} This site has been identified in SINV capsid protein between residues 94 and 105 and coincides with a predicted site for genome RNA binding.³⁰⁸ It has also been suggested that the core might be primed for uncoating by exposure to low pH, which causes the core to become unstable.^{303,306} This exposure to low pH could occur in the endosome because both E1 and 6K have been proposed to have ion channel properties.^{158,169,304} However, studies using pre-formed cores microinjected into naïve cells demonstrated that these cores do uncoat presumably devoid of conditions of low pH.²⁵⁸ Whether these cores interact with ribosomes to promote disassembly and release of genome RNA remains to be shown.

FIGURE 22.7. Model of alphavirus fusion. **A:** Native virions with E1 represented by two circles (domains I and III) and an extended oval (domain II), and E2 in the background and covering the E1 fusion peptide (star). **B:** Low pH triggers dissociation of E1 and E2 and fusion peptide exposure. **C:** Low pH and cholesterol-dependent insertion of the fusion loop into the target membrane, aligning E1 and promoting trimerization. **D:** Fold-back process by which domain III and the stem region move toward the fusion loop. **E:** Folding of domain III and the stem region against domain II of the trimer pulls the transmembrane domains toward one another distorting the viral membrane. **F:** Opposing dome-like deformations in the two membranes leads to mixing of the outer leaflets (termed hemifusion). **G:** Close opposition of the fusion peptides and transmembrane domains resolve into the fusion pore. Translation and the Role of Viral-Encoded Replication Proteins

The genome RNA serves as an mRNA for the synthesis of the nonstructural or replication proteins (Fig. 22.4). These are produced by two polyproteins that originate translation at nucleotide 60 in SINV.²⁶⁸ The smaller but more abundant polyprotein P123 terminates translation at an opal codon following 1,897 amino acids. Readthrough of the opal codon occurs with a low frequency (~10% to 20%) and results in the production of the larger P1234 polyprotein. Not all alphaviruses have a termination codon to control the production of the two polyproteins, but mutagenesis of the opal codon in SINV

adversely affects replication.¹⁴⁴ Processing of the polyproteins occurs through the action of a virus-encoded protease located within the nonstructural protein 2 (nsP2).^{39,91,92} The processing of the polyprotein to generate precursor and end-product nsP's is believed to regulate the synthesis of viral RNAs.^{35,137,250} Translation of the structural polyprotein proceeds through a subgenomic mRNA that is initiated near the coding region for the C-terminus of P1234. The subgenomic mRNA is 3' co-terminal with the genome RNA and is produced later in the infection.²⁶⁸

Initial studies of the replication proteins used temperature-sensitive mutants that were conditional lethal for viral

TABLE 22.1 Translation Products of Alphaviruses (Sindbis Virus)

Protein	Size (aa)	Function
Nonstructural Proteins		
nsP1	540	Methyltransferase and guanylyltransferase; anchors replicase complex to membranes
nsP2	807	NTPase, helicase, RNA triphosphatase, protease responsible for processing of non-structural polyprotein
nsP3	556	Phosphoprotein with unknown function(s) but important for minus-strand synthesis; contains macro domain and SH3-binding regions
nsP4	610	RNA-dependent RNA polymerase (RdRp), terminal transferase
Structural Proteins		
Capsid	264	Encapsidates genomic RNA to form nucleocapsid core; carboxyl domain is an autocatalytic serine protease
E3	64	N-terminal domain is uncleaved leader peptide for E2; E3 + E2 = pE2.
E2	423	Presents the major neutralizing epitopes and is responsible for receptor binding
6K	55	Leader peptide for E1, enhances particle release, putative ion channel
TF	70	TransFrame (TF) protein, putative ion channel, enhances particle infectivity, expression prevents synthesis of E1
E1	439	Responsible for membrane fusion activity

replication. These studies established complementation groups and identified specific functions of the replication proteins.²⁶⁴ Four complementation groups were identified, and these correlated with the four nsP's. Once sequence information was available, motifs were identified that verified function and permitted phylogenetic relationships between other virus families to be established. This resulted in the suggestion of an alphavirus-like superfamily that contained RNA virus members from several plant families and argued for an evolutionary relationship between them.^{2,267}

The nsP's are multifunctional proteins with their known activities shown in Table 22.1. However, it is likely that additional unknown activities exist. Guanine-7-methyltransferase and guanylyltransferase activities necessary for mRNA and genome RNA capping have been shown to reside within nsP1.^{127,173,174} This capping activity is distinct from cellular capping enzymes in substrate preference.⁶ Several genetic studies have confirmed the identity of amino acids critical for the methyltransferase function, but the domain required for guanylyltransferase activity has not been identified and may flank the conserved methyltransferase domain.^{8,227} A *ts* mutant that mapped to Ala348 of nsP1 in SINV demonstrated a role of the protein in minus-strand RNA synthesis.⁸⁷ A defect in minus-strand synthesis has also been seen with mutations in nsP4, and some of these have been complemented with changes in

nsP1 at residues 349 and 374, suggesting sites for nsP1 and nsP4 interaction.⁴³ nsP1 is the only alphavirus nonstructural protein that has been shown to be membrane associated.^{128,203} The membrane association has been suggested to occur by a palmitoylated cysteine at residue 420 (in SINV).^{7,127} Mutations that disrupt palmitoylation did not alter the distribution of replication complexes and show only modest reductions in growth. However, nsP1 can still bind to membranes through a patch of positively charged and hydrophobic amino acids between residues 245 and 264.⁹ Nuclear magnetic resonance spectroscopy of a corresponding peptide suggests that this sequence can form an amphipathic α -helix that can interact with liposomes.¹²⁹ This membrane anchoring of the replication complex associated with nsP1 is probably required for efficient replicase activity.

The largest of the replication proteins is nsP2, with a length of about 800 amino acids. The N-terminal half of the protein has helicase, nucleoside triphosphatase, and RNA triphosphatase activities,^{78,79,221,281} whereas the C-terminal half contains a novel cysteine protease domain and a nonfunctional methyltransferase domain.^{263,282} The structure for the C-terminal two domains of the VEEV nsP2 was solved by Watowich and colleagues using x-ray crystallography (Fig. 22.8).²³⁴ The structure shows that the active site of the protease is positioned close to the interface between the two domains. Although related to proteases papain and cathepsin X, the fold of the nsP2 protease domain appears to be unique and a new

FIGURE 22.8. Structure of the Venezuelan equine encephalitis virus nsP2 protease. A ribbon diagram showing the protease colored from blue (N-terminus) through red (C-terminus) representing residues N468 to S787. The catalytic dyad residues, C477 and H546, are found in the N-terminal protease domain (**top**), whereas the methyltransferase-like domain (**bottom**) comprises the C-terminal domain. (Courtesy of Dr. Joyce Jose; generated in PyMol using the PDB coordinates 2HWK from Russo AT, White MA, Watowich SJ. The crystal structure of the Venezuelan equine encephalitis alphavirus nsP2 protease. *Structure* 2006;14:1449–1458.)

form of cysteine protease structure. Although having a similar tertiary structure with known methyltransferases such as FtsJ, the S-adenosylmethionine (SAM) substrate binding site is very different in backbone alignment and sequence, arguing against any methyltransferase activity. However, by mapping several previously identified *ts* mutants affected in RNA synthesis onto the C-terminal domain, it was suggested that the domain functions as an RNA-binding scaffold that regulates protease activity and RNA synthesis.^{233,234}

The nsP2 protein has a nuclear localization sequence that results in 50% of the protein reaching the nucleus,^{222,223} and it has been reported that nsP2 of VEEV undergoes both nuclear import as well as export.¹⁷⁷ Abrogation of the signal results in a slightly defective virus, but at least in SFV the mutant has lost neuropathogenesis, arguing for a role of nsP2 in host interactions.²²⁰ Studies have identified a role for nsP2 from the Old World alphaviruses in the induction of cytopathic effects and the establishment of persistent infections, and is discussed later in the chapter.^{41,55} In addition, experiments have provided a link between nsP2 and the host response, resulting in shutoff of minus-strand RNA synthesis.²⁴⁰ Genetic studies identified conditional lethal mutations demonstrating RNA-defective phenotypes that implicated nsP2 in the regulation of minus-strand synthesis and in the initiation of subgenomic RNA synthesis.^{37,87,241} Furthermore, the role of the protease activity to regulate the temporal control of RNA synthesis has been well established and is described later.^{35,137}

The function of the nsP3 protein remains obscure, although genetic analyses indicate that it plays a role in RNA synthesis and neurovirulence.^{131,276,297} The protein is highly conserved among alphaviruses at its N-terminus, whereas the C-terminal 200 amino acids are rich in serine and threonine residues. The protein is phosphorylated on serines and threonine; however, this modification is not required for replication, and its function in the virus life cycle is not known.^{130,143,204,284,285} The protein has a weak affinity for membranes and will associate with them when expressed in the absence of the other nsPs.^{202,284} A crystal structure of both the CHIKV and VEEV N-terminal 160 residues of nsP3 confirmed previous suggestions that this region contains a macro domain (the VEEV structure is shown in Fig. 22.9).^{80,163} These domains function as ADP-ribose binding modules and have also been shown capable of single-strand RNA binding. The exact function(s) of the macro domain awaits additional studies. Although the C-terminal end of nsP3 is not well conserved, a proline-rich sequence found in most alphaviruses was identified as a target site for Src-homology 3 domain containing proteins amphiphysin-1 and amphiphysin-2.¹⁸⁵ Disruption of the binding sequence by mutation or reduction of amphiphysin-2 by RNAi reduced replication in both SINV and SFV. It is unclear how this interaction influences RNA replication; however, the amphiphysins have been implicated as membrane-binding proteins, involved in endocytosis, and membrane trafficking, and the virus may usurp these functions to facilitate RNA synthesis.

The core of the virus replication complex is the RNA-dependent RNA polymerase (RdRp) that maps to nsP4.^{87,121} Interestingly, because of the opal codon in SINV, synthesis of P123 is significantly greater than the level of P1234 and thus nsP4 levels are lower than that of the other nsPs. Furthermore, modifications that increase the synthesis of nsP4, such as the removal of the opal termination codon, result in reduced virus replication.¹⁴⁴ The majority of the protein from the C-terminus constitutes the RdRp domain based

FIGURE 22.9. Structure of the Venezuelan equine encephalitis virus nsP3 macro domain. A ribbon diagram showing the nsP3 macro domain colored from blue (N-terminus) through red (C-terminus) representing residues A1 to E160. The structure consists of a six-stranded β -sheet ringed by three α -helices. (Courtesy of Dr. Joyce Jose; generated in PyMol using the PDB coordinates 3GQE from Malet H, Coutard B, Jamel S, et al. The crystal structures of Chikungunya and Venezuelan equine encephalitis virus nsP3 macro domains define a conserved adenosine binding pocket. *J Virol* 2009;83:6534–6545.)

on homology with other polymerases and predicted secondary structures.¹¹¹ A short region exists at the N-terminus that lacks a counterpart in other viral polymerases, and it has been suggested that it might be a binding domain for the other nsPs.^{87,249} The N-terminus of nsP4 also contains a conserved tyrosine residue, and this serves to make the protein unstable in infected cells.^{36,248,252} deGroot et al.³⁶ examined the degradation of nsP4 and showed that it was degraded by the N-end rule pathway. It has been suggested that free nsP4 is rapidly degraded, whereas nsP4 that is a component of replicase complexes is protected and relatively stable. Therefore, it was not a surprise that attempts to express the full-length nsP4 in heterologous systems were initially unsuccessful. However, expression of nsP4 lacking the first 97 amino acids was successful, and this truncated nsP4 displayed a terminal adenylyltransferase activity.²⁷⁵ This terminal transferase activity was suggested to play a role in the maintenance of the poly (A) tract at the 3' end of positive-strand RNAs. The nsP4 protein was subsequently expressed as an N-terminal small ubiquitin-like modifier (SUMO) fusion protein that was cleaved after purification, and nsP4 was shown to possess de novo minus-strand synthesis activity that was dependent on the correct 3' end of positive-strand template.²²⁹ Proteomic studies have been used to identify host proteins that might interact with nsP4 during virus infection.³³ In this study the authors demonstrated that a total of 29 host proteins were associated with nsP4 in a temporally regulated pattern. Among the proteins identified, two proteins known as GTPase-activating protein SH3-domain binding protein 1 and 2 (G3BP1 and G3BP2) were

also shown to interact with nsP2 and nsP3.³² However, the role of these proteins is unclear; they may function to reduce the pool of RNAs available for translation by recruiting the viral RNA to the stress granule pathway.

Transcription and Replication of Genomic Nucleic Acid

Alphavirus-infected cells produce three species of RNAs: genome plus-strand RNA, complementary minus-strand RNA, and sub-genomic mRNA. The synthesis of these three species is tightly regulated by the availability of specific nsP's (Fig. 22.10).^{35,136,137} Replication is initiated on the cytoplasmic surface of endosomes and lysosomes on structures termed cytopathic vacuoles.⁶¹ All four nsP's can be found associated with each other and within these vacuoles.¹²⁶ In elegant studies by Strauss et al.³⁵ it was shown that proteolytic site selection controlled the processing of the nsP's and determined the components of the replicase complex. This was accomplished by assessing cleavage-site preferences and determining which enzymes (nsP2 or its precursors) could affect processing. Additional studies by the Sawicki laboratory using temperature-sensitive mutants established the biochemical nature of the replicase complex.^{15,37,239,242} In complementary work, the Rice laboratory carried out *in vivo* replica-

tion studies using nsP's expressed in a vaccinia vector to discern the functional complexes.^{135–137} Despite earlier problems, they were successful in developing a system for template-dependent initiation of SINV.¹³⁴

RNA replication begins with the initiation of minus-strand synthesis. This event requires the 3' CSE and host proteins/factors.^{56,72,90,123} *In vitro* studies using polymerase extracts suggest the poly (A) tract may not serve as template for the initiation of minus-strand synthesis, although the details of this initiation event are not known.⁸⁹ Minus-strand synthesis requires P123 or P23 and nsP4, but a cleavage-defective P1234 is not functional.^{135–137,250} Similarly, in the vaccinia system, expression of the individual nsP's was not sufficient for complex formation and minus-strand synthesis.^{135,136} As minus-strand synthesis continues, nsP's continue to be translated and concentrations of the protease precursors increase. Cleavage at the nsP1–nsP2 and nsP2–nsP3 junctions results in the switch over to plus-strand synthesis, presumably by a change in the conformation and composition of the replicase complex (Fig. 22.10). Synthesis of minus strands by the replicase requires continuous protein synthesis, and it has been suggested that nsP2 engages the host response by using the RNase L-dependent pathway to inhibit host cell translation.^{82,240} As

FIGURE 22.10. The conserved sequence elements (CSEs) and nonstructural proteins involved in alphavirus genome replication. A: A schematic of minus-strand synthesis from a plus-strand template. A protein complex composed of P123 and nsP4, and presumably host proteins (not shown), initiate synthesis of the minus strand from the 3' end of the genome. CSE4, a 19nt element, is found just upstream of the polyA tract. CSE4 is thought to act as a promoter for minus-strand synthesis, perhaps via a cyclization event with CSE2, a 51nt element located within the nsP1 coding region (not shown). **B:** A schematic of full-length 49S genomic and 26S subgenomic RNA syntheses from a minus-strand template. An accumulation of P123 allows processing of P123 polyproteins in *trans* into the individual nonstructural proteins. Presumably, the altered conformation of the replicase complex shifts template preference to the minus strand. CSE1, comprising the first 44nt of the 5' genome, acts as a promoter for synthesis of full-length 49S genomic RNA from a minus-strand template, perhaps in conjunction with CSE2. Fully processed replicase complexes also associate on the CSE3 element, which span the 3' end of the nsP4 coding sequence and the junction region between the nonstructural and structural genes. These CSE3-associated replicase complexes efficiently transcribe the 26S subgenomic message. Note that a replicase complex composed of nsP1, P23, and nsP4 may also be capable of plus-strand synthesis (not shown). (Courtesy of Jonathan Snyder.)

with most plus-strand RNA viruses, synthesis is asymmetric with minus-strand synthesis about 2% to 5% the level of plus-strand genome RNA.²⁹⁸

Although the viral protein composition of the minus- and plus-strand replicases is known, the role of host proteins in the complex is not. From studies with the CSEs, host cell-dependent effects were observed and several host proteins were shown to bind to the conserved RNA elements.^{56,193,194,195} Furthermore, Fayzulín and Frolov⁴⁴ showed that although the 51 nt CSE is dispensable in mammalian cells, in mosquito cells mutations have a deleterious effect. Interestingly, adaptive mutations occur in the 5' NTR, as well as in nsP2 and nsP3, suggesting their involvement in CSE function. Frolov et al.,⁵⁶ using chimeric templates and *trans*-competition experiments, showed that the 5' NTR is a component of the promoter for not only plus-strand synthesis, but also for minus-strand synthesis. From these data, they proposed a model for the initiation of minus-strand RNA synthesis that requires the 5' and 3' ends of the genome RNA to be brought together. This would be accomplished using components of the host translational machinery, which is involved in cap and poly (A) binding. Despite the attractiveness of the model, the lack of a purified

reconstituted system for RNA synthesis has hampered progress in understanding alphavirus RNA replication.

The synthesis of the subgenomic mRNA is controlled by a minimal promoter element that spans from -19 to +5 relative to the start of mRNA synthesis. A larger fragment from -98 to +14 provides three- to sixfold more activity and constitutes the fully active promoter.²¹⁴ As with the 5' and 3' CSEs, the subgenomic promoter appears to interact with host factors, as mutations in the promoter have differential effects, depending on replication in vertebrate versus invertebrate hosts.^{101,102,311} This promoter has been extensively employed in gene expression and replicon studies using alphaviruses, including the use of multiple tandem promoters.^{19,57,59}

Perhaps the most informative studies on alphavirus replication in recent years have emerged using advanced imaging techniques. These approaches have shed light on the spatial and temporal assembly of replication complexes. Most intriguing is the observation that membrane-derived structures competent for RNA synthesis appear to form initially at the plasma membrane (Fig. 22.11). Studies from both SFV and SINV demonstrate that the membrane invaginations referred to as spherules first accumulate on the plasma membrane and are

FIGURE 22.11. Assembly of alphavirus replication complexes. **A:** Replication complexes consisting of P123 and genome RNA are found at the plasma membrane. With the addition of nsP4 (**B**), the RNA-dependent RNA synthesis (RdRp), synthesis of double-stranded DNA (dsRNA) occurs (**C**) along with the formation of membrane spherules. Upon processing of P123 (**D**), replication complexes switch to the synthesis of genomic and subgenomic RNA. As replication continues (**E** and **F**) free nsP1, nsP2, and nsP3 are found, with the latter protein associating with specific host proteins and nsP1 remaining membrane associated. At later stages, multiple spherules coalesce into cytopathic vacuoles type 1 (CPV-1) within the cytoplasm. (Adapted by Thomas Edwards and R.J.K. with permission from Drs. Elena Frolova and Ilya Frolov.⁶⁰)

later internalized using the actin–myosin network.^{60,262} These structures appear to contain all of the nonstructural proteins as well as double-stranded RNA but are devoid of any structural proteins. Structures known as cytopathic vacuoles type 1 and type 2 (CPVI and CPVII) were described previously as containing the replication proteins and viral glycoproteins, respectively.^{61,202} The role of CPV2 appears to guide the glycoproteins to the site of budding; however, the role of CPV1 for RNA synthesis is not as clear. CPV1 structures form later in RNA replication, probably as a result of spherule recruitment from the plasma membrane, but it has been suggested that they may not be the major site for viral RNA synthesis at least in mammalian cells.⁶⁰

Assembly of Nucleocapsid Core, Glycoprotein Synthesis, and Processing

The subgenomic RNA, which is made at approximately three times the level of the genomic RNA, is translated to produce the structural or virion proteins.²¹⁶ The order of translation is capsid-PE2(E3+E2)-6K-E1 (Fig. 22.2). Translation of the structural polyprotein is enhanced due to the presence of a hairpin secondary structure in the subgenomic mRNA between residues 77 and 139.⁵⁹ The polyprotein is processed by host and viral proteases to generate the authentic structural proteins that will end up in the virion, and the membrane topology of the glycoproteins is shown in Figure 22.12. The capsid protein is translated first and is released by proteolysis immediately after the ribosome clears the junction between it and PE2. The capsid functions as an autoprotease, and sequence and mutational analyses suggested that the C-terminal domain of the capsid contained a serine-like protease.^{10,86} This hypothesis was confirmed by the x-ray crystal structure of the C-terminal domain from SINV.²⁹ The protein has a chymotrypsin-like fold, with His141, Asp163, and Ser215 forming the catalytic triad. Interestingly, the C-terminal resi-

due, Trp264, remains in the active site pocket and presumably prevents transcleavage by the protease. With the self-cleavage of the capsid protein, the new N-terminus of the polyprotein now contains a signal sequence for translocation of the PE2 sequence across the endoplasmic reticulum (ER) membrane.⁶⁹ Additional signal sequences are present at the C-terminus of E2, permitting translocation of 6K, and at the C-terminus of 6K, permitting translocation of E1 (Fig. 22.12). The expression of TF protein, which contains the first 43 amino acids of 6K, and then shifts to the -1 reading frame that prevents the synthesis of E1.⁴⁷ Proteins E1, E2, 6K, and TF are transmembrane proteins, whereas E3 is released from most alphavirus particles following cleavage of its PE2 precursor.^{95,210,211,232,236} SFV retains the cleaved E3 with the virion; however, it is unclear whether it has a postcleavage function.³²¹

Following autoproteolysis, the capsid protein transiently associates with the ribosome, and assembly into a core particle appears to be both rapid and efficient, with no observed intermediates.^{259,279} A specific “packaging sequence” has been identified in the genome RNA in SINV that promotes encapsidation of RNA into the assembling core.³⁰⁰ In SINV, this sequence has been identified as nucleotides 945 to 1076, and attempts to identify the nature of the recognition element have met with limited success.¹⁵⁰ However, there is conservation of structural and functional components of packaging signal across diverse alphaviruses.¹¹⁷ The packaging sequence on the genome RNA is recognized by residues 81 to 113 in the capsid protein.^{71,299} A deletion of residues 97 to 106 results in a failure to efficiently package genome RNA, although cores still form with heterologous RNA incorporated.¹⁹² Although most alphaviruses package their genomes with high efficiency, Aura virus has been described as an alphavirus that packages its subgenomic mRNA as well.^{230,231} The development of alphaviruses as gene expression vectors has prompted much investigation into the packaging requirements, and in VEEV, packaging has been shown to

FIGURE 22.12. Schematic model for the configuration of the E1 and E2 glycoproteins in the membrane. **Left:** Configuration of the glycoproteins after signalase cleavage of 6K and E1, but before cleavage of PE2. **Right:** Configuration of glycoproteins after the maturation cleavage of PE2 into E3 and E2. Note the *dark red jagged lines* on the cytoplasmic side of E2 and 6K that represent palmitoylation sites (PALs). Glycosylation sites are indicated by CHO. Signal sequences are indicated as *colored rectangular blocks*. Stop-transfer sequences are indicated as *colored cylinders*. The shapes of the polypeptides do not imply their native configuration. (Courtesy of Dr. Joyce Jose.)

require expression of nsP123, although the mechanism and the generality of this requirement have not been shown.²⁸⁶

Although *in vitro* systems for core assembly have been described, the stepwise assembly process has not been clearly elaborated.^{272–274,301,302} The capsid protein requires the addition of nucleic acid to initiate the assembly process, and in the presence of full-length wild-type protein, assembly proceeds rapidly. Using a truncated capsid protein, the initial step appears to involve a protein dimer complexed with RNA.^{273,274} Cores are found in the cytoplasm and attached to membranes, probably through their interaction with E2 (reviewed in^{68,110}). Cytoplasmic cores have a well-defined size and $T = 4$ icosahedral symmetry, similar to *in vitro* assembled cores, but not identical to the well-ordered $T = 4$ symmetry in cores found within virus particles.^{178,196} However, the symmetry of the core does not necessarily dictate the symmetry of the virion, and it is likely that the icosahedral architecture of the glycoprotein scaffold is the driving force behind the strict $T = 4$ organization of alphavirus.^{52,138,207} This is supported by the observation from Forsell et al.,⁵³ who produced a SFV capsid protein with a deletion in residues 40 to 118. This mutant was unable to assemble cores, but virus particles were produced that had the expected $T = 4$ symmetry.

In parallel with the formation of the nucleocapsid in the cytoplasm, the envelope proteins that were translocated into the ER are processed and undergo posttranslational modifications (Fig. 22.5). High mannose chains are added to all potential N-linked glycosylation sites, and the oligosaccharide chains are trimmed depending on the availability of the site.^{243,245} Palmitoylation occurs at several sites in E2 and 6K/TF.^{17,64} In a set of elegant studies, Brown et al. showed that E1 and PE2 undergo a complex series of folding intermediates.^{22,120,180,181} These intermediates require chaperones and disulfide bond formation and exchange. The E1 and E2 glycoproteins form a heterodimer in the ER, but it is not known whether higher-order oligomerization takes place here.^{218,321} Oligomerization of PE2 and E1 is also a requirement for the transport of the glycoproteins, but the presence of the capsid (CP) is not required.^{70,105,157} It has been shown that PE2 oligomerizes with a partially folded intermediate of E1 and that this oligomerization is sufficient for the proteins to exit the ER. After the heterodimer reaches the trans-Golgi network, but prior to arrival at the plasma membrane, PE2 is cleaved by furin.³⁴ This cleavage is required for virion entry and fusion activation in new cells, although revertants can be readily isolated that suppress the requirement for cleavage.^{96,211}

Virion Budding

The final stage of the virus life cycle is the effective interaction between the capsid protein and the glycoproteins to promote virus budding. Thin-section electron microscopy of infected cells has shown a clustering of nucleocapsid cores at the plasma membrane at sites of budding but it is likely that the interaction occurs earlier, perhaps in the vicinity of CPVII.²⁶¹ All evidence suggests that a proper interaction between the cores and glycoprotein spikes is required for budding.¹⁰⁹ When the glycoproteins have been expressed in the absence of the capsid protein, virus-like particles have not been observed. In SFV, virions have been shown to bud from specific sites in polarized cells,²²⁵ and virus has been reported to bud intracellularly in insect cells.¹⁷⁵ There also appears to be a requirement for cholesterol in the membrane to support budding,^{159,164} and host

cell lipid metabolism has also been implicated.¹⁸⁶ Several systems have been reported that show the exogenously produced capsid cores can be introduced into naïve cells expressing the viral glycoproteins and particles can be released, suggesting that RNA synthesis is not required for budding.^{26,258}

The interaction between the capsid protein and the envelope glycoproteins has been investigated extensively, with most of the available data coming from molecular genetic and structural studies.^{109,271} X-ray crystallography of the capsid protein identified a hydrophobic pocket that was occupied by the amino-terminal arm of a neighboring capsid protein. The nature of the arm residues bound in the hydrophobic pocket suggested that a tyr-ala-leu motif found in the cytoplasmic domain of the E2 glycoprotein might function in a similar manner and bind into the capsid protein pocket.^{133,256} An extensive number of mutagenesis experiments involving SFV and SINV have established residues of the E2 cytoplasmic domain that were important for the interaction with the tyrosine, which is conserved in the alphaviruses, as an important one.^{64,109,270,319} E2 peptides have also been used to inhibit budding, suggesting residues involved in process and similar peptides were shown to bind to capsids.^{30,170} In addition, cryo-EM studies have shown that the cytoplasmic domain of E2 clearly extends down into the core to the site of the hydrophobic pocket.^{271,179,271,318} As was mentioned previously, deletions that disrupt the accumulation of nucleocapsid cores do not prevent budding because lateral interaction between the glycoproteins appear to be the driving force as long as capsid interactions do occur.²⁸⁷

The 6K protein, which has been estimated at 5 to 10 molecules per virion, has been implicated in the budding process and in the formation of virions.^{63,64} Removal of 6K from the genome of SFV did not influence the formation of the E1–E2 heterodimer or its transport to the cell surface, but it did reduce budding.¹⁴⁹ Other studies have shown that mutations in 6K can influence glycoprotein trafficking and virion assembly.²³⁸ E2 and 6K appear to interact, as mutations in 6K can be suppressed by mutations in E2,¹⁰⁷ and chimeric viruses containing an SINV glycoprotein and an RRV 6K are highly defective for virus formation.³¹⁴ Recently, it has been shown that a frameshift occurs at a low frequency during translation of the region encoding 6K resulting in the production of the TF protein shown in Figure 22.13.⁴⁷ The TF protein shares 47 amino acids with 6K and contains the transmembrane domain that has been implicated in channel formation. The remaining 23 residues are unique to TF and since there is a –1 frameshift followed by a termination codon, no E1 is produced from this polyprotein. Preliminary data suggest that TF also has a role in virus replication and is incorporated into the virion but whether its function(s) overlaps with 6K is not yet known.

Effects on the Host Cell

Alphaviruses have a wide host range and must interact with a variety of cellular receptors, either ubiquitous or unrelated molecules. Because the nature of these receptors is largely unknown, equally unknown is the signaling that such molecules might engage in following virion attachment and early steps in entry. Clearly, the response of most vertebrate cells to viral infection is distinct from the response of invertebrate cells. However, in both cases there appears to be a balance between the needs of the virus to effectively propagate and the needs of the host to control virus infection and dissemination. Host

FIGURE 22.13. Ribosomal frameshifting during translation of the 26S subgenomic RNA yields a newly described protein, TransFrame (TF). **A:** Sequence alignment of various alphaviruses demonstrates the conservation of a putative slippery site motif within the 6K gene (underlined for Sindbus virus). The coordinate of the first nucleotide of the slippery site is indicated in parentheses for each virus. **B:** The typical protein products obtained from normal translation of the 26S subgenomic RNA (**top**), and the protein products obtained in the case of a frameshift event (**bottom**). Note that the amino terminal regions of the 6K and TF proteins share the same sequence. **C:** A model of the putative membrane topology of the mature 6K and TF proteins. The N- and C-termini are denoted. 6K (**left**) contains both a transmembrane anchor (cylindrical), and a membrane spanning region that acts as the signal sequence for E1 (rectangular). TF (**right**) contains only the transmembrane anchor (cylindrical); the frameshift event prevents production of the E1 signal sequence. (Courtesy of Jonathan Snyder.)

macromolecular synthesis is inhibited in vertebrate cells shortly after infection (reviewed in 268). Host protein synthesis is shut off at 3 hours after infection, although virus protein translation continues unabated. This has been an intensive area of investigation, and four mechanisms for shutoff have been proposed: (a) an altered intracellular environment such as K^+ concentration that would favor viral translation, (b) direct competition for translational machinery, (c) inhibition of cellular translation by the capsid protein, and (d) inhibition of translation by one of the nonstructural proteins. The development and use of replicon systems that contain only the *cis*-acting replication signals and the coding region for replication proteins suggested that the structural proteins were not responsible for translational shutoff.⁵⁸ Furthermore, studies investigating the establishment of persistence identified changes in SINV nsP2, at Pro726 to serine, which reduced cytopathic effects of the virus.⁵⁵ A variety of studies suggest that alphavirus infection

promotes the double-stranded RNA-activated protein kinase (PKR)-dependent and PKR-independent pathways to reduce host cell translation.^{66,235} Mutations in nsP2 suggest that the shutoff of host cell transcription and translation are distinct events and strongly influence the decreased production of a α/β interferon.⁸¹ However, the role of nsP2 in host cell shutoff appears to function only in the Old World alphaviruses. It has been shown that in VEEV and other New World alphaviruses that a region of the capsid protein encompassing residues 33-68 and not nsP2 is responsible for transcriptional shutoff and cytopathogenicity.⁶⁷ This region of the VEEV capsid protein has also been shown to be responsible for nuclear trafficking of the protein to the nucleus.¹²

Most infections by alphaviruses of vertebrate cells in culture lead to the induction of apoptosis.¹³⁹ Apoptosis of infected neurons is a major determinant of neurovirulence, as demonstrated for SINV.¹⁴² In contrast, mosquito cells can undergo a variety of effects from persistent infections to cell death caused by necrosis.¹¹² It has also been possible to establish persistent infection of vertebrate cells using defective interfering particles, followed by genetic changes to the helper virus in nsP2.⁴¹ An alternative method was used by selecting for replicons that were noncytopathic to BHK cells, and again, amino acids substitutions were detected in the coding region for nsP2,⁵⁵ suggesting a major role for this protein in modulating the virus–host interaction.

A number of antiviral proteins produced in infected cells have been described for the alphaviruses. A small hydrophobic peptide of 3,200 D was shown to be produced in persistently infected mosquito cells, and this peptide could activate an antiviral state.¹⁶¹ This peptide induced the synthesis of a 55-kD protein and inhibited the replication of alphavirus RNA.¹⁶⁰ The rat zinc-finger antiviral protein (ZAP), originally identified as a retrovirus resistance protein, was shown to inhibit multiple alphaviruses.¹⁶ This protein inhibited viral translation by binding to viral mRNA, although its exact mechanism of action is not known.⁸³ It is likely that many additional proteins, such as interferon-stimulated genes, will demonstrate direct antiviral activity and might be exploited to control alphavirus infection.

Defective Interfering Genomes and Replicon Systems

Defective interfering (DI) genomes replicate and are packaged in the presence of helper virus, and retain all *cis*-acting sequences necessary for RNA replication. Several alphavirus DI genomes have been molecularly characterized, and all retain the 3' CSE that was previously described. The 5' end of the DI genomes was found to be more heterogeneous, with the 5' CSE, cellular transfer RNA (tRNA) sequences, or the 5' 142 nucleotides from the subgenomic mRNA located at the 5' end of the DI RNA. The study of DI genomes provided a powerful genetic tool to identify the location and function of required *cis*-acting sequence elements.¹⁴¹ The development of DI genomes for genetic purposes gave way to the construction of replicons, which supported RNA replication but were incapable of infection of new cells because they lacked the structural proteins.^{140,244,313} The structural proteins could be supplied by additional helper RNAs so that the replicons could be packaged and used to efficiently infect target cells.¹⁹

The alphavirus replicon has become a standard gene expression system. The system has proven useful for examining

protein expression in heterogenous systems and the development of vaccines.²⁴⁴ SINV, SFV, and VEEV replicons have been widely used and can allow for targeting to specific cells.^{148,214,244} By introducing a mutation in nsP2 that renders the replicon noncytopathic, continuous replication in the absence of cell death can occur for SINV.⁵⁵ For VEEV, mutations in the 5' nontranslated region and nsP3 were also required for persistent infection by the replicon.²⁰⁵ Multiple subgenomic promoters can be employed for the expression of several proteins of interest in a regulated fashion. To further reduce the chance of recombination between replicon and helper RNAs to generate an infectious genome, tricomponent replicon systems have been developed that can produce at least 1,000 packaged replicons per cell.⁴⁵

RUBIVIRUS REPLICATION

Virion Structure and Entry

Although once considered a close cousin of the alphaviruses, molecular analyses of rubella virus have revealed significant differences.⁵⁴ Whereas rubella virions are similar to alphaviruses in protein composition and morphology, the particles have yet to yield to high-resolution structural analysis, and it is unlikely that the particles share the property of icosahedral symmetry with the alphaviruses. The rubella virion is composed of three structural proteins that share the same name as alphaviruses, yet differ in amino acid sequence.⁴⁰ The virions are pleomorphic in shape and are around 60 to 70 nm in diameter.¹⁸² The two type I envelope glycoproteins, E1 and E2, form heterodimers, and have 13 and 7 amino acids on their inner cytoplasmic face. All three structural proteins are membrane associated with the C-terminus of the capsid containing the signal sequence for E2.¹⁹⁰ The structural proteins are cleaved by signal peptidase, with the signal sequence for E1 present at the C-terminus of E2.¹⁰³ The capsid protein is a phosphoprotein of 293 or 300 amino acids, depending on which AUG codon is used to initiate the polyprotein.¹⁶⁵

Rubella virus is restricted to growth in humans and is not transmitted by insects, as are the alphaviruses. However, the virus can replicate in a wide range of mammalian cell types and can infect experimental animals producing subclinical results. Thus, like alphaviruses, a ubiquitous cellular receptor may function in entry, although none has yet been identified. The virus also appears to enter through a receptor-mediated endocytosis pathway with membrane fusion promoted by an acidified endosome,¹¹³ and a class II fusion mechanism is expected.

Transcription, Translation, and Genome Replication

The placement of rubella virus in the family *Togaviridae* implies a common genome structure and replication strategy. Complete nucleotide sequences are available for several strains of rubella virus.^{40,212} The 9,762 nucleotide genome RNA contains a 5' terminal 7-methylguanosine and a 3' terminus that is polyadenylated.^{191,294} The genomes of rubiviruses and alphaviruses are compared in Figure 22.4, and a more complete discussion of rubella replication is provided in Chapter 24. The replication proteins P150 and P90 are encoded by the genome RNA, whereas the structural proteins are derived from the subgenomic mRNA. Although there is no amino acid sequence

homology among the structural proteins, limited homologies do exist within the replication proteins.⁴⁰ The construction of a rubella virus complementary DNA (cDNA) clone from which infectious RNA could be generated permitted molecular genetic studies on the virus that were, up until then, quite limited.^{213,294}

Three species of RNA are synthesized in infected cells: complementary minus-strand RNA, genome RNA, and subgenomic mRNA. On infection, the genome RNA is translated into a 200-kD polyprotein that is cleaved by a virus-encoded protease.⁵⁰ Unlike its alphavirus counterpart, the rubella enzyme is a metalloprotease that contains zinc-binding domains, and it cleaves P200 in trans.²⁹⁵ Virus replication complexes can be found in association with cellular membranes. Virus-specific vacuoles have been identified and colocalize with lysosomal markers, similar to those found for alphaviruses.¹²⁵ There is a close association between these replication complexes, identified with antibodies to P150, and ER and Golgi membranes, presumably to facilitate translation and packaging of genome RNAs.²²⁴

Attempts to identify cellular proteins that might participate in RNA replication have focused on proteins that bind to the 5' and 3' NTRs. A 5' stem-loop structure predicted to form on the plus-strand RNA was shown to bind to the La autoantigen. Several cellular proteins were shown to bind to the 3' NTR.^{183,184} One of these proteins was identified as calreticulin, although decreased binding of calreticulin did not correlate with reduced virus replication.²⁵⁵ The nonstructural protein P90 has been shown to bind to the retinoblastoma protein Rb through an Rb-binding motif.¹³ Mutation of this motif reduces virus replication, but it is unclear whether the defect is related to a reduction in binding.⁴⁹

The capsid protein has also been implicated in RNA replication. It has been shown to complement a replication defect resulting from a deletion of 169 amino acids from P150.²⁷⁷ Exactly how this might function is not known, but the amino terminal 88 residues of the capsid were sufficient for complementation, and these might function by binding to RNA. In addition, the capsid protein has been shown to influence the replication of rubella replicons,²⁵ although once again the mechanism is not known. The capsid protein has also been shown to bind to mitochondrial matrix protein p32 and the proapoptotic protein Bax.¹⁰⁶ The function of capsid in binding these proteins is to prevent apoptosis and enhance RNA replication.

Virus Assembly

A packaging signal has been located between nucleotides 347 and 375 of the genome RNA, and it interacts with capsid residues 28 to 56.¹⁵⁴ Phosphorylation of the capsid protein occurs and has been suggested to act as a regulatory mechanism to prevent binding of nonviral RNAs to the capsid.¹³² With the retention of the capsid protein signal sequence at its C-terminus, the capsid remains associated with the ER membrane. This association may be important for ensuring close connectivity with the envelope glycoproteins through their transmembrane domains. Glycoproteins E1 and E2 are believed to have functions similar to their alphavirus counterparts, although rubella virions bud into the Golgi.¹⁰⁴ Virions undergo a maturation step after Golgi budding that may release the capsid signal sequence because morphologic changes occur in the core of the virion.²²⁴ The structures of the mature and immature rubella virions await structural techniques but will probably require

electron tomography, as they lack the icosahedral symmetry present in the alphaviruses.

PERSPECTIVES

Our knowledge of togaviruses has grown dramatically thanks in large part to the ability to genetically manipulate these relatively “simple” plus-strand RNA viruses. Insights into alphaviruses have been obtained more quickly than for rubella virus due to their greater replication efficiency in cultured cells and their well-organized virions. Structural studies of the alphaviruses have progressed rapidly, leveraging the icosahedral nature of the virus particles and the ability to obtain large quantities of homogeneous preparations. The ability to express capsid proteins in heterologous systems has facilitated both structural and biochemical studies of capsid structure and its assembly pathway. The structure determinations of the native and postfusion forms of the E1 protein have provided exceptional insights into the entry process and the structure of the virion. The atomic structures of the E1 and E2 heterodimer, in both low pH and neutral forms, have provided insight into the sequential entry process employed by these viruses.

Significant gaps still persist in understanding the replication process of the togaviruses. Although the protease domain of nsP2 and the macro domain of nsP3 have been determined, the full-length proteins have proven difficult to express in large quantities, to purify to homogeneity, and to crystallize. Furthermore, it is expected that the functional entities will be complexes of viral and probably cellular proteins that will further complicate structural analyses. The ability to reconstitute purified and functional replication complexes will be an important milestone to decipher RNA replication. In contrast, significant progress has been made in understanding the cellular response to viral infection and the recruitment of cellular proteins to promote or inhibit the virus replication complex. Systems-level studies to evaluate the total cellular environment altered in virus infection are beginning to yield a comprehensive picture of how the virus perturbs and subjugates the cell. The use of advanced and real-time optical imaging as well as electron tomography promises to provide a temporal and spatial view of virus infection. However, most studies continue to rely on standard cell culture systems and it will be important to verify what occurs in more natural target cells such as neurons.

With the growing knowledge of togaviruses, their utility in gene expression and gene therapy continues to be exploited and expanded. Future directions that will further benefit this system will be in understanding the nature of the cellular receptors and the structure of the E2 protein that is involved in binding these receptors. With this knowledge, newly designed alphavirus vectors will be engineered to specifically and efficiently target the replicon to cells and tissues of interest.

Perspective

The genus *Alphavirus* includes 29 species that can be classified antigenically into at least eight complexes (Table 23.1). Alphaviruses are geographically restricted in their distributions and have been found on all continents and on many islands. In nature, alphaviruses cycle between invertebrate insect vectors and vertebrate hosts. For most alphaviruses, the insect vectors are mosquitoes; however, other hematophagous arthropods, such as lice or mites, are vectors for a few. The vertebrate hosts are generally mammals or birds, although fish are hosts for the aquatic alphaviruses. In general, the pathogenic alphaviruses are divided into the viruses that cause human disease characterized by rash and arthritis, primarily found in the Old World, and viruses that cause encephalitis, primarily found in the New World. For many alphaviruses, no human or veterinary disease has been recognized. Larger mammals, such as humans and horses, that tend to develop severe or fatal disease are often dead-end hosts unimportant to the endemic virus transmission cycles but can be important for sustaining epidemics.

HISTORY

Records of diseases almost certainly attributable to alphaviruses date to the 18th and 19th centuries, when epidemics of fatal encephalitis in horses in the northeastern United States and outbreaks of arthritis in Southeast Asia were recognized and recorded.^{111,300,788} The first clear report of epidemic encephalitis comes from the summer of 1831, when 75 horses died in Massachusetts.³⁰⁰ Over the next 100 years, several local outbreaks of encephalitis in horses were noted along the Atlantic seaboard of the United States and in the Pampas region of South America.⁶⁸³ However, the first alphavirus to be cultured was western equine encephalitis virus (WEEV). This virus was isolated in 1930 from the central nervous system (CNS) tissues of 2 horses involved in an epidemic of equine encephalitis in the San Joaquin Valley of California.⁵²² Eastern equine encephalitis virus (EEEV) was isolated from the brains of affected horses in New Jersey and Virginia in 1933.⁷⁸⁶ Both diseases occurred in summertime epidemics, suggesting an arthropod vector, and

TABLE 23.1 Alphaviruses, Abbreviations, Biological Features, and Association with Disease

Virus (abbreviation)	Antigenic complex	Principal vertebrate reservoir host	Geographic distribution	Human disease	Animal disease
Aura (AURA)	WEE	?	South America

Western equine encephalitis (WEE)	WEE	Birds, mammals	North America, South America	Fever, encephalitis	Horse, emu
Whataroa (WHA)	WEE	Birds	New Zealand, Australia		

in 1933, Kelser showed WEEV transmission by mosquitoes.³⁸⁸ In 1936, an epizootic of equine encephalitis occurred in the Guajira region of Venezuela; the virus isolated was not neutralized by antisera against EEEV or WEEV and was designated Venezuelan equine encephalitis virus (VEEV).⁴²⁰

Summertime epidemics of polyarthritis were recognized in Australia and New Guinea in 1928,^{183,572} and subsequent outbreaks were reported in Northern Europe, Africa, and Southeast Asia.⁷²⁷ It is likely, of course, that the alphavirus-induced

arthritic diseases are much older than these dates but were not clearly described or differentiated from more prevalent infections in these regions, such as dengue. This is considered to be particularly true of outbreaks of chikungunya virus (CHIKV) that have occurred in India and Southeast Asia over the past 200 years.^{111,788} Viruses associated with epidemic polyarthritis were eventually isolated, both from mosquitoes collected in the areas of human disease and later from humans. The first of these viruses was isolated in 1952 from a pool of *Culex* spp.

mosquitoes collected near Sindbis, Egypt.⁷⁸² However, it was many years before Sindbis virus (SINV) was linked to human disease.⁴⁹³

The first clear association of an alphavirus with arthritic disease came in 1953, when CHIKV was isolated in Tanzania from the blood of people with severe arthritis.⁶⁶⁸ During the next several years, several viruses that cause arthritis, often accompanied by a rash, were isolated in Africa, Australia, and South America.^{122,537,884} These viruses were added to the growing list of arthropod-borne (arbo) viruses, defined by the World Health Organization in 1967 as “viruses which are maintained in nature principally, or to an important extent, through biological transmission between susceptible vertebrate hosts by hematophagous arthropods; they multiply and produce viremia in the vertebrates, multiply in the tissues of arthropods, and are passed on to new vertebrates by the bites of arthropods after a period of extrinsic incubation”.⁶²¹

In 1954, arboviruses were divided by Casals and Brown into three serologic groups—A, B, and C—based on cross-reactivity in hemagglutination inhibition (HI) tests.^{556,621} EEEV, WEEV, and VEEV constituted the group A arboviruses. A second cross-reacting set, including dengue, St. Louis encephalitis, and yellow fever viruses, constituted the group B arboviruses, and the nonreactive viruses were designated group C. As viruses became classified on the fundamental properties of the virion and the genome, the group A viruses became the *Alphavirus* genus within the *Togaviridae* family of enveloped RNA viruses.

INFECTIOUS AGENTS

Alphaviruses are enveloped plus-strand RNA viruses with icosahedral symmetry (Fig. 23.1). The virions are 60 to 70 nm

in diameter and sensitive to ether and detergent. Cryo-electron microscopy structures are available for many.^{18,418,496,549,618,722,901–903} The RNA is contained within a capsid formed by a single protein arranged as an icosahedron with $T = 4$ symmetry. The nucleocapsid is enclosed in a lipid envelope derived from the host cell plasma membrane that contains the viral-encoded glycoproteins E1 and E2. These proteins form heterodimers that are grouped as trimers to form 80 knobs on the virion surface. Glycoproteins are arranged such that 240 copies of each interact with 240 copies of capsid protein.

The 49S genome is composed of a single-strand, non-segmented, capped, and polyadenylated message sense RNA that is infectious. Complete sequence information is available for representatives of all currently known *Alphavirus* species.^{129,161,206,219,297,402,431,434,437,518,764} The genomes are 11 to 12 kb in size and are organized with the nonstructural proteins (nsPs) at the 5′ end and the structural proteins at the 3′ end. The nsPs are translated from genomic RNA and the structural proteins from a subgenomic RNA.⁷⁶⁵ Four nsPs function to replicate the viral RNA and produce the subgenomic RNA (see Chapter 22).

Five potential structural proteins (C, E3, E2, 6K, and E1) are encoded in the subgenomic RNA as a polyprotein, and an additional transframe protein (TF) is produced by −1 ribosomal frameshifting within the 6K coding region.^{141,215} The N-terminal portion of C is basic and is presumed to bind the viral genomic RNA, whereas the more conserved C-terminal portion interacts with other copies of the C protein to form the nucleocapsid and also interacts with the cytoplasmic tail of E2.^{765,901}

E3 is a small, cysteine-rich glycoprotein that serves as a signal sequence for pE2 (the precursor containing E3 and E2), mediates proper folding of E2, and is necessary for pE2 to

FIGURE 23.1. Three-dimensional (3D) reconstruction of the Venezuelan equine encephalitis virus (VEEV) virion. A: Radially colored 3D reconstruction of VEEV showing the E1 basal triangle (green) and E2 central protrusion (blue) for each spike. Scale bar: 10 nm. **B:** One asymmetric unit of the virus containing four unique copies of E1 (magenta), E2 (cyan), E3 (orange), and capsid (CP, blue). The cryo-electron microscopy densities for the viral membrane (yellow) and genomic RNA (green) are also displayed at slightly lower isosurface threshold. (Courtesy of Wah Chiu; reproduced with permission from Zhang R, Hryc CF, Cong Y, et al. 4.4 Å cryo-EM structure of an enveloped alphavirus Venezuelan equine encephalitis virus. *EMBO J* 2011;30:3854–3863.)

FIGURE 23.2. Domain structure of the glycoprotein spike. Schematic diagram of the E1pE2 heterodimer drawn “untwisted” to show the domains positioned with respect to one another and their connectivity. Domains of E1 (I, red; II, yellow; III, blue; fusion loop, orange) and pE2 (A, cyan; B, dark green; C, pink; E3, gray) are shown. Ct, C-terminus; Nt, N-terminus. (Courtesy of Felix Rey; reproduced with permission from Voss JE, Vaney MC, Duquerroy S, et al. Glycoprotein organization of chikungunya virus particles revealed by x-ray crystallography. *Nature* 2011;468:709–712.)

heterodimerize with E1 for transport to the cell surface.^{468,599} As part of the pE2-E1 heterodimer, E3 prevents premature activation of E1.^{362,840,844} E3 is cleaved from E2 by furin in the trans-Golgi, remains associated with the spike under acidic conditions, and is usually shed when virions bud from the cell surface.^{737,904}

The E2 glycoprotein is a transmembrane protein that has two or three N-linked carbohydrates and contains the most important epitopes for neutralizing antibody. E2 is organized into three immunoglobulin domains (A, B, and C) (Fig. 23.2). Domain A (residues 1–132) is at the center and top of the heterotrimer and has receptor and neutralizing antibody-binding sites. Domain B is at the spike tip, and C is toward the viral membrane.^{455,840} The intracytoplasmic portion interacts with the capsid and has a second stretch of hydrophobic amino acids and myristoylation sites that tether it to the inner surface of the membrane.

The 6K protein serves as a signal peptide for E1, is cleaved from E1 and E2 by signal peptidase, and is important for budding, and small amounts are incorporated into the virion.^{238,461} The E1 protein has one or two N-linked carbohydrates, a short (one or two residue) intracytoplasmic tail, and a positionally conserved internal hydrophobic stretch of amino acids in the N-terminal portion that serves as the fusion peptide for virion entry into the cell. E1 is organized into three β -sheet-rich domains (I, II, and III) similar to the flavivirus E protein with the internal fusion loop at the tip of domain II^{253,443} (see Fig. 23.2). The function of TF has not yet been defined but can be incorporated into virions.²¹⁵

Propagation and Assay in Tissue Culture

Initial isolations of alphaviruses were accomplished by intracerebral inoculation into suckling mice—a host very susceptible to infection with most alphaviruses.^{335,668,689,781,782,867,884} Many alphaviruses can also be isolated and propagated efficiently in primary chick embryo fibroblasts (CEFs) and in various continuous mammalian cell lines such as human epithelial (HeLa, MRC5) cells, baby hamster kidney (BHK) cells, monkey kidney (Vero) cells, and mouse fibroblast and neuroblastoma cells^{108,581} (Fig. 23.3).

FIGURE 23.3. Effects of Sindbis virus infection on vertebrate cells.

A: Cytopathic effects (CPE) of rounding, shrinkage, and cytoplasmic blebbing in baby hamster kidney (BHK) cells infected at a low multiplicity. **B:** Electron micrograph of an infected BHK cell showing chromosomal condensation and cytopathic vacuoles.

Most alphaviruses will form plaques on susceptible mammalian or avian cells under an agar overlay. Mosquito cell lines also support replication, although often without cytopathic effect (CPE).^{635,761,763,803} The first plaque assay of an animal virus was performed using WEEV on CEF cells,¹⁹⁰ and plaque assay remains a convenient and sensitive way to quantify infectious virus. Plaque size has been used to differentiate strains and is determined by the type of overlay used, by relative virus binding to negatively charged sulfated polysaccharides present in the overlay, and by replication efficiency.^{87,96,775}

Biological Characteristics

Hemagglutination

Alphaviruses can hemagglutinate avian (e.g., goose, chicken) erythrocytes,^{581,684} and hemagglutination has been used as a method for quantifying virus and HI for measuring antiviral antibody.¹⁴⁴ Hemagglutination requires prior exposure of the virus to acidic pH, depends primarily on the E1 glycoprotein, and reflects binding of the fusion domain of the E1 glycoprotein to lipids in the erythrocyte membrane.^{130,144,829,873} E2 also participates in hemagglutination because some monoclonal

antibodies (MAbs) specific for E2 also have HI activity.^{67,640} The HI test has been useful for determining antigenic relationships among alphaviruses.¹⁰⁷

Cellular Receptors

Binding of virus to the cell surface and entry into the cell is a multistep process that depends on virus glycoproteins E1 and E2, cell surface molecules, low pH in the endosome, and fusion of membrane lipids. Variations in any of these components will affect the efficiency of infection and the likelihood that any particular cell will become infected *in vivo*. Virus-specific attachment to cells is primarily a function of the E2 glycoprotein. The important role for E2 in initiating virus–cell interaction is evidenced by the ability of anti-E2 MAbs to inhibit binding to cells,^{96,474} of anti-idiotypic antibodies to E2-specific MAbs to recognize putative virus receptors on cells,^{823,852} and of amino acid changes in E2 to alter virus binding to cells of different types.^{189,438}

Identification of specific alphavirus receptors has been difficult and may be complicated by experimental use of virus strains that are adapted to replicate in tissue culture.⁴¹¹ Because each alphavirus infects a wide range of hosts, often including birds, mammals, and mosquitoes, they must either use an evolutionarily well-conserved cell surface molecule or multiple molecules as receptors. None of the alphavirus receptors identified to date appears to be used exclusively, suggesting the possibility of several receptors. Alternatively, alphaviruses may use receptor-coreceptor combinations to achieve wide host range and the specific tropisms observed *in vivo*.

The first alphavirus receptor to be identified was the major histocompatibility complex (MHC) class I molecule receptor for Semliki Forest virus (SFV) on mouse and human cells.³¹⁵ This molecule is not absolutely required because cells lacking MHC molecules can still be infected with SFV.⁵⁸³ The high-affinity laminin receptor is a receptor for SINV on BHK cells and a potential receptor for SINV and VEEV on C6/36 mosquito cells.^{474,850} Again, this molecule appears to account for only a portion of the total virus interaction with the cells studied and does not contribute to SINV binding to avian cells.⁸⁵⁰ Ross River virus (RRV) uses the $\alpha_1\beta_1$ integrin on HeLa cells for binding.⁴²⁶ SINV and VEEV can use natural resistance-associated macrophage protein (NRAMP) for binding to insect and mammalian cells.⁶⁶⁴ The type of cell in which the virus is grown can also influence initial virus–receptor interactions. For instance, SINV grown in mosquito cells is enriched in high-mannose carbohydrates that bind the C-type lectins DC-SIGN and L-SIGN on the surface of dendritic cells (DCs).⁴¹⁰

Heparan sulfate (HS), a ubiquitously expressed glycosaminoglycan is an important initial binding molecule for certain strains of many alphaviruses. The use of HS is selected for by virus passage in vertebrate cells. However, wild-type strains of EEEV bind HS, so this property is not exclusively determined by passage in tissue culture.²⁴² For these viruses, addition of heparin or lactoferrin, treatment of cells with heparinase, or the use of cells deficient in HS decreases binding to cells and plaque formation.^{59,96,242,312,409,411,426,740,843} Interaction with HS—a highly sulfated, negatively charged molecule—probably explains the effects of ionic strength and charge on the attachment of virus to cells.^{499,501,611} The heparin-binding domain of the E2 glycoprotein is on domain A and overlaps a neutralizing epitope (see Fig. 23.2). Changes toward more positively charged amino acids

in the region around E2–70 increase the efficiency of attachment to cells in tissue culture.^{59,97,242,411}

Entry requires endocytosis followed by a conformational change in the trimer of E1–E2 heterodimers induced by exposure to low pH.^{313,729,739,879} The E1 fusion peptide is protected in the virion heterotrimer by the B domain of E2, and this association is stabilized by E3.^{455,840} When exposed to acidic pH, E1 dissociates from E2 and forms stable E1 homotrimers in the presence of cholesterol-containing membranes. During this conformational change, the fusion peptide is exposed and inserted into the outer leaflet of the lipid bilayer.^{83,252,253} Fusion with the cell membrane to initiate infection depends on the presence of a membrane potential and sphingolipid.^{314,570,899}

Effects on Vertebrate Cells

Alphaviruses replicate rapidly in most vertebrate cell lines with the release of progeny virus typically within 4 to 6 hours after infection. At the time of virus entry, there is an increase in permeability perhaps owing to pore formation by the E1, 6K, and/or TF proteins.^{492,871,872} Insertion of newly synthesized glycoproteins into the plasma membrane renders infected cells capable of adenosine triphosphatase (ATP)-dependent polykaryocyte formation on exposure to acid pH.³⁸⁹ Infection causes extensive CPE characterized by cell rounding, shrinkage, and cytoplasmic blebbing (see Fig. 23.3A), with the death of infected cells within 24 to 48 hours.^{449,635} Alphavirus-induced CPE has been linked to shut off of host cell transcription and translation,²⁴⁶ endoplasmic reticulum (ER) stress,⁵⁷⁴ and induction of apoptosis.^{20,26,257,270,351,449,656,699} The ability of alphaviruses to induce cell death, combined with the ability to express heterologous genes and activate natural killer (NK) cells, has led to their development as potential oncolytic agents.^{344,454,552,633,634,808,809,830}

Shut off of host cell functions in Old World viruses (e.g., SINV, SFV) has been linked to the effects of nuclear nsP2 and in New World viruses (e.g., VEEV, EEEV) to the effects of C.^{14,32,247} Activation of protein kinase R (PKR) results in phosphorylation of eIF2 α , which shuts down host protein synthesis without affecting translation of viral 26S subgenomic RNA.⁸³⁴ Alphavirus escape from eIF2 α phosphorylation is owing to the presence of a hairpin loop structure in the subgenomic messenger RNA (mRNA) downstream of the initiation codon that allows the 40S ribosome to initiate translation in the absence of eIF2.^{185,804,834} This initiation process utilizes host cell factors ligatin and MCT-1/DFNR⁷³⁸ and does not depend on mTOR signaling.⁵³⁰ Alphavirus-induced inhibition of host protein synthesis can also be PKR-independent perhaps through late suppression of mTOR.^{265,530}

The apoptotic process is associated with blebbing of the plasma membrane, condensation of nuclear chromatin, and formation of apoptotic bodies (see Fig. 23.3B). Viral proteins are concentrated in the surface blebs from which budding continues to occur.⁶⁶⁵ This process does not hamper, and may enhance, virus replication because inhibition of apoptosis usually decreases virus yield.^{445,458,699}

The mechanism(s) by which alphaviruses induce apoptosis is not completely understood and likely differs with virus and type of target cell. Apoptosis of cultured cells can be initiated at the endosomal membrane during SINV fusion.³⁶⁴ Membrane-bound sphingomyelinases are activated releasing ceramide, an efficient inducer of cellular apoptosis.^{363,366} SFV-induced apoptosis requires RNA synthesis and accumulation^{777,828} and is

independent of p53.^{258,828} Other events in alphavirus-induced cell death often include early activation of poly(adenosine diphosphate [ADP] ribose) polymerase,^{564,596} activation of pro-apoptotic Bcl-2 family member proteins Bad or Bak,⁵³⁹ loss of mitochondrial membrane integrity, and release of cytochrome c.^{50,828} Cellular caspases are activated with cleavage of caspase-3 substrates and fragmentation of chromosomal DNA.⁸²⁵

Apoptotic death is accelerated by glycoprotein-induced ER stress,^{50,234,574} sphingomyelinase deficiency,⁵⁶⁷ low levels of extracellular Ca^{++} ,⁸²⁵ expression of Bax,⁵⁷⁴ and activation of Bid.⁸²⁸ Alphavirus-induced apoptosis can be slowed or prevented by expression of ceramidase,³⁶³ altered Ras signaling,^{365,413} expression of p21^{WAF1/CIP1},³³⁸ expression of Bcl-2 family member and interacting proteins,^{270,449,451,458,539,552,574,699,826,828} expression of the ER stress protective protein Parkin,⁵⁷⁴ mutation of nsP2,^{246,574} phosphorylation of PKC δ ,⁹¹⁰ inhibition of constitutive expression of NF κ B,⁴⁶² and caspase inhibition.^{565,695,828}

Alphavirus-induced vertebrate cell death can also occur by caspase-independent, nonapoptotic mechanisms. Alphaviruses efficiently shut down protein, ribosomal RNA (rRNA) and mRNA synthesis in infected cells,^{246,264,510,556} deplete nicotinamide adenine dinucleotide (NAD) and energy stores,^{199,825} and induce dysfunction of Na^+K^+ adenosine triphosphatase (ATPase) causing loss of membrane potential and changes in intracellular cation concentrations.^{51,827} Genome replication without structural protein synthesis can induce cell death.⁸²⁸ For Old World viruses, expression of nsP2 alone is cytotoxic, and this property is independent of its protease activity and can be separated from the effects of nsP2 on host transcription.^{187,233,246,247,264,507,605,777} Although immature neurons die by apoptosis, mature neurons are more resistant to apoptotic cell death.^{257,307} This resistance is attributable to an intrinsic ability to suppress virus replication.^{120,835} Mature motor neurons, infected by virulent strains of virus, die by a necrotic process and are not protected from death by Bcl-2 family member proteins.^{307,393} Autophagic clearance of viral proteins may promote neuronal survival.⁵⁸⁸

Persistent infection can occasionally be established in mammalian cell cultures *in vitro*. Mouse fibroblasts producing interferon (IFN), or BHK cells with a high concentration of defective interfering particles, can establish SINV persistent infection.^{345,869} Infection with SINV or SINV replicons that have mutations in the C-terminal methyl transferase-like domain of nsP2 results in reduced viral RNA synthesis, decreased CPE, and persistent infection in some vertebrate cell lines.^{7,187,233,235,507,605} Persistent infection can also be established if the cell infected is resistant to virus-induced apoptosis.^{90,449,824,835}

Effects on Invertebrate Cells

Studies of alphavirus infection of cell lines derived from *Aedes albopictus* (e.g., C6/36, U4.4) and *Aedes aegypti* (e.g., Aag2) larvae demonstrate differences in alphavirus replication between vertebrate and invertebrate cells. The time course of virus replication is similar; however, frequently, virus matures within vesicular structures and virions are released by exocytosis rather than at the plasma membrane.^{523,763} Virions are relatively deficient in cholesterol and have detectable differences in structure.^{296,310,754} There is only a modest effect on host gene expression,^{225,696} and persistent noncytopathic infection, or death by a nonapoptotic process,³⁸³ is more likely than in vertebrate cells.

The uncloned lines derived from *Ae. albopictus* larvae contain many types of cells with properties representative of different mosquito tissues. Lytic infection occurs in clones that support high levels of virus replication,^{523,803} whereas persistent infection is associated with a short period of relatively high virus replication followed by a decrease in virus production and often in the numbers of cells in the culture that are producing virus.^{164,547,548} The decrease in virus production is not associated with activation of the signal transducer and activator of transcription (STAT), immune deficiency (IMD), or toll insect innate response pathways but is associated with decreased processing of the nonstructural polypeptide and expression of the protease inhibitor TEPII.^{225,547} Lytic infection can also be induced by viruses engineered to express death-inducing insect proteins such as reaper or michelob_x.⁸⁴⁹ Transcriptional analysis of persistently infected cells shows an increase in mRNAs associated with vesicle formation and the Notch signaling pathway.⁵⁴⁷

RNA interference (RNAi) is an important insect defense mechanism, and SFV infection of U4.4 or Aag2 cells leads to production of virus-derived small interfering RNAs (viRNAs) derived from replicative double-stranded (dsRNA) that are unevenly distributed across the genome and variable in efficiency for mediating antiviral RNAi.⁷³⁶ This RNAi signal can spread from cell to cell and inhibit replication.³⁷ The RNAi pathway is defective in C6/36 cells⁷⁴; however, the IMD, and not the toll innate response pathway, can suppress SINV replication in these cells.⁴¹

Superinfection Exclusion

Vertebrate and invertebrate cells infected with one alphavirus cannot be productively infected with the same, or a closely related, alphavirus at a later time. Exclusion is established after translation of the nsP genes of the first virus to enter. The superinfecting genome can be translated but not replicated,⁷⁶² probably owing to the presence of the transacting nsP2 protease that prematurely cleaves the replicase polyprotein required for minus-strand synthesis.³⁸⁴

Antigenic Composition

All alphaviruses are related and share common antigenic sites, as revealed by HI and complement fixation (CF) tests with polyclonal immune sera¹⁰⁷ and by cytotoxic T-cell lysis of infected cells.^{465,550} Antigenic cross-reactivities may confer some cross protection and interfere with sequential alphavirus immunizations.^{106,181,277,465,508} These cross-reactivities formed the basis for the original classification into the group A arboviruses and continue to be a valuable means for initial identification and classification of alphaviruses.¹⁰⁷ Closely related viruses within a serogroup form a complex. Seven broad antigenic complexes have been identified within the alphavirus serogroup: Barmah Forest, eastern equine encephalitis (EEE), Middelburg (MID), Ndumu (NDU), Semliki Forest, Venezuelan equine encephalitis (VEE), and western equine encephalitis (WEE).^{427,626,806} A few viruses remain unclassified and will probably form one or more additional complexes (see Table 23.1). The Barmah Forest, EEE, MID, and NDU complexes each contain only a single virus, whereas the Semliki Forest, VEE, and WEE complexes include several viruses. Viruses within each complex can be subtyped using reactivity with MAbs, kinetic HI, or neutralization assays.⁹⁸

Antibodies to E1 are more likely to cross-react with other alphaviruses than are antibodies to E2.^{67,343,892} This is

FIGURE 23.4. Neutralization escape mutations and positions affecting host range and tissue tropism mapped on the Venezuelan equine encephalitis virus spike. Neutralizing antibody escape mutations are displayed as yellow spheres on the spike with epitope written in the spheres. E1 is shown in ribbons and E2 in surface rendering using the colors defined in Figure 23.2. The **left panel** shows a top-down view of the spike, the **middle panel** shows the spike from the side, and the **right panel** shows the far right dimer from the middle panel. (Courtesy of Felix Rey; reproduced with permission from Voss JE, Vaney MC, Duquerroy S, et al. Glycoprotein organization of chikungunya virus particles revealed by x-ray crystallography. *Nature* 2011;468:709–712.)

consistent with the documented sequence conservation in the E1 protein. Competitive binding assays using MAbs have identified approximately seven epitopes on the E1 glycoproteins of SINV, SFV, WEEV, and VEEV.^{67,343,519,662,703} Most E1 epitopes are not exposed on the virion surface but are present on the surface of infected cells or on acid-exposed virions.^{15,282,320,519,703} These transitional epitopes map to domain III in a region buried at the spike interfaces⁸⁴⁰ (Fig. 23.4). The *in vitro* biological activities of antibodies to E1 include HI, neutralization of virus infectivity, and inhibition of fusion.^{15,67,282,343,703} Neutralizing epitopes map to domains I, II, and III.^{282,455}

Antibodies to E2 are usually alphavirus specific. Competitive binding assays using MAbs identify four to five epitopes on the E2 glycoproteins of SINV, SFV, RRV, and VEEV.^{67,394,519,586,662} *In vitro* biological activities of antibodies to E2 include HI, neutralization of virus infectivity, and blocking of virus binding to the cell surface.⁶⁶² Many anti-E2 MAbs have both neutralizing and HI activity, suggesting that these functions overlap.²⁸² Neutralization escape mutants, naturally occurring variants, λ gt11 expression libraries, site-directed mutagenesis, and recombinant viruses have been used to identify amino acids contributing to the various epitopes on E2 and have identified two major neutralizing sites^{704,758,851} that have been mapped onto the crystal structure of the E1-E2 heterodimer and trimerized spike and are in domain B.^{8,282,367,455,840} (see Fig. 23.4). This is an exposed hydrophilic region that often includes an N-linked carbohydrate. There are linear, as well as conformational, determinants in this region because these MAbs frequently react in Western blots and recognize λ fusion proteins, and antibodies to peptides from this region are protective against challenge.⁸⁵¹

The second neutralizing epitope on E2 appears to be primarily conformational and is in domain A. This region is responsible for binding to HS and is obscured if pE2 is not cleaved.^{96,675,840} Visualization by cryo-electron microscopy of the binding of HS and MAbs to this epitope on SINV and RRV identifies the domain A knob on the glycoprotein spike.^{742,902}

Evolution and Phylogeny

Alphaviruses, which replicate in arthropods, birds, reptiles, fish, and mammals, derive from a single unknown protoalphavirus and are part of the alphavirus superfamily of viruses. Viruses in this superfamily, including many RNA plant viruses, have a similar genetic organization and replicase proteins but diverse coat proteins.^{417,766} Among alphaviruses, amino acids important in secondary structure (e.g., cysteines and those close to one another in adjacent β sheets and α helices) have been conserved for the glycoproteins E1, E2, and E3, consistent with a similar three-dimensional structure of the virion for all.²¹⁹ The most variable regions of the genome are in the C-terminus of nsP3 and the N-terminus of C.²¹⁹ Highly conserved regions in the nsP1 and nsP4 genes have allowed development of primers to detect a broad range of alphaviruses by reverse transcription polymerase chain reaction (RT-PCR).^{201,290} Sequence information from the entire genome generally groups the viruses similarly to that derived by antigenic analysis (Fig. 23.5) and has detected at least one recombination event.²⁹⁷ Criteria for species demarcation of alphaviruses combine genetic, ecological, and antigenic information. Species generally have distinct transmission cycles and differ by more than 23% at the nucleotide level and 10% in amino acid sequence when E1 genes are compared.

The origin of the alphaviruses is unclear. Partial genome sequencing has suggested origins both in the Americas and in the Old World.^{107,267,434,626,859} Recently, comparison of whole genome sequences from all known alphaviruses has suggested an origin from the louse-borne aquatic alphaviruses⁵¹⁹ (see Fig. 23.5). All of these scenarios require repeated movement across the globe to explain the current virus distributions.

Like other RNA viruses, alphaviruses undergo genetic change primarily by accumulation of point mutations in the genomic RNA; however, deletions and duplications also occur.^{1,217} Mutation occurs at a rate that is slower ($1\text{--}7 \times 10^{-4}$ substitutions/nucleotide/year) than is estimated for other RNA viruses,^{93,146} presumably because fitness must be maintained in both insect vectors and vertebrate hosts.¹⁴⁷ Recombination

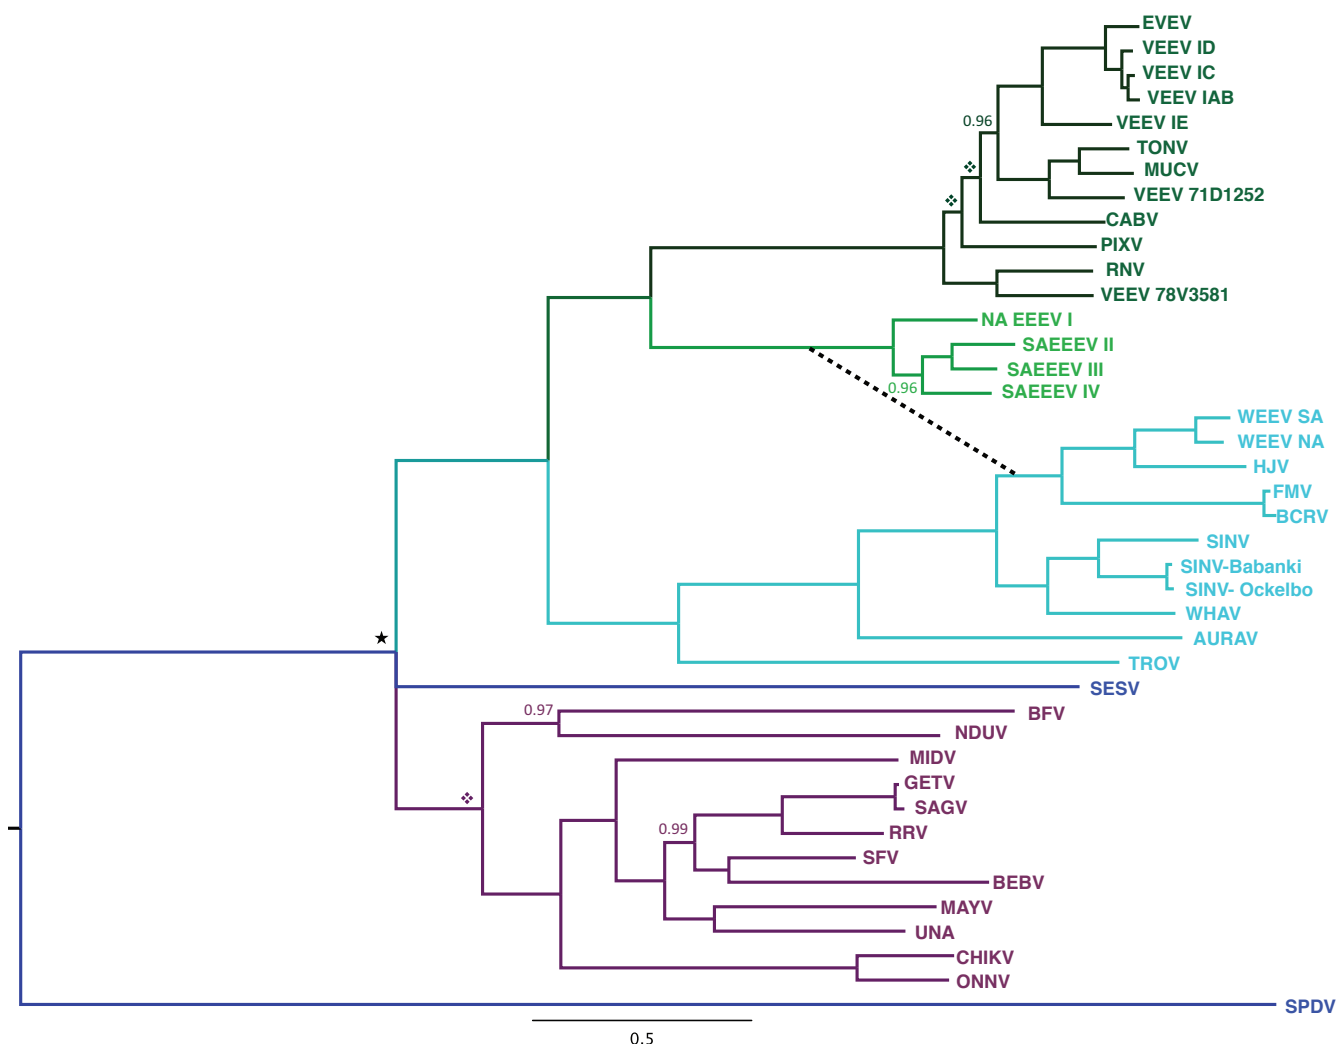

FIGURE 23.5. Alphavirus phylogenetic tree produced using the E2, 6K, and E1 structural protein genes and Bayesian methods with midpoint rooting. The tree includes representatives from all alphavirus species, and the *dashed line* indicates the recombination between ancestors of Sindbis and eastern equine encephalitis viruses that led to the western equine encephalitis virus (WEEV) group. Roman numerals indicate major subtypes of some species, and scale indicates 50% nucleotide sequence divergence. All posterior probabilities were 1 except as indicated; nodes with a diamond had posterior probabilities less than 0.9, and nodes with a star had no posterior support. A similar tree utilizing full-length sequences without the WEEV recombinant group showed a similar topology except Middelburg virus was basal to chikungunya and o'nyong-nyong viruses, and Una, Mayaro, Semliki Forest, and Bebaru viruses were grouped separately together with Getah, Sagiyama, and Ross River viruses.²¹⁹ (Courtesy of Scott Weaver; from Forrester NL, Palacios G, Tesh RB, et al. 2012. Genome-scale phylogeny of the alphavirus genus suggests a marine origin. *J Virol* 2012;86(5):2729–2738.)

between alphaviruses can be demonstrated *in vitro* but is infrequent and usually puts the chimeric virus at a replicative disadvantage.^{93,146} However, successful recombination has occurred at least occasionally in nature because WEEV resulted from recombination between EEE- and Sindbis-like viruses (see Fig. 23.5) at the junction of E3 and E2, an event that is estimated to have occurred thousands of years ago.^{219,421,766}

Alphaviruses replicate in and are transmitted horizontally by a wide range of invertebrate, primarily mosquito, species. However, each virus usually has a principal or preferred vector for the enzootic cycle. Most alphaviruses can infect various vertebrates but have birds, mammals, or fish as their primary amplifying and reservoir hosts (see Table 23.1). The specific

invertebrate vector and vertebrate host used by an alphavirus will contribute significantly to determining the geographic distribution of that virus. Experiments modeling evolution *in vitro* show that fewer mutations accumulate if replication alternates between vertebrate and invertebrate cells, although diversity, fitness, and adaptability are greater with serial passage.^{149,150,153,276,856} Experiments employing *in vivo* passage show that serial passage in mosquitoes increases mosquito infection and that passage in vertebrates produces higher viremias; however, alternately passaged viruses do not change fitness.¹⁴⁹ It is hypothesized that short transmission seasons and host mobility influence alphavirus genetic diversity and evolution in a geographic region.^{146,858} Viruses using avian enzootic hosts

(e.g., EEEV, WEEV, SINV) extend over wide geographic regions and evolve as a few highly conserved genotypes, whereas viruses using mammalian enzootic hosts with a more limited range of dispersal (e.g., RRV, VEEV) evolve within multiple geographically restricted genotypes.^{490,688}

Some strains of alphaviruses associated with epidemics or epizootics are antigenically and biologically distinguishable from enzootic strains. Phylogenetic evidence indicates that, at least for VEEV and WEEV, the virulent epizootic strains evolve by mutation from avirulent viruses being maintained in the enzootic cycle.^{23,61,629,657}

PATHOGENESIS AND PATHOLOGY IN VERTEBRATES

Excellent and well-studied model systems exist for several alphaviruses, and much of our detailed knowledge about alphavirus pathogenesis comes from investigations in mice. Information from these models will be combined where appropriate with information from studies of humans with alphavirus-induced disease to deduce the pathogenesis of infection. Specifics will be covered in sections on the individual viruses.

Entry

The primary mode of alphavirus transmission to vertebrates is through the bite of an infected insect, most often a mosquito. Mosquitoes salivate during feeding and deposit virus-infected saliva extravascularly.⁸¹⁹ Saliva virus titers are highest early after the mosquito is infected and decline, along with transmission rates, after 1 to 2 weeks; however, mosquitoes remain infected for life.^{525,833} The high-mannose glycans on virus from mosquitoes inhibits induction of IFN by myeloid DCs,⁷¹⁸ and proteins in saliva further facilitate transmission by skewing the host cellular immune response toward Th2 cytokines.⁷⁹⁴

Sites of Primary Replication

The initial sites of virus replication vary with the virus and host. Mice have received the most extensive study. After subcutaneous inoculation, viruses may infect skeletal muscle or fibroblasts at the local site (e.g., EEEV, WEEV, SFV, RRV, SINV, and Getah virus) or be taken up by and infect Langerhans cells in the skin (e.g., VEEV)^{287,325,466,553} (Fig. 23.6). Langerhans cells and DCs transport virus to lymph nodes draining the site of inoculation that also may become infected.^{242,487} *In vitro*, human DCs are susceptible to infection with VEEV but not to infection with CHIKV or EEEV^{241,573,702,707,753}; thus, the importance of DC infection after mosquito inoculation is likely to differ with the infecting virus.

Spread

Alphaviruses induce a substantial plasma viremia in their amplifying hosts and in hosts susceptible to disease (Fig. 23.7). The ability to mount and sustain a viremia depends on the continued efficient production of virus, delivery of virus into the vascular system, and slow clearance from the blood. Animal studies have shown that small plaque viruses are generally less virulent because they are cleared more rapidly from the circulation than are large plaque viruses.^{354,360,623} This phenomenon is related to the ability of small plaque viruses to bind HS and

FIGURE 23.6. Basic steps in alphavirus infection of vertebrates. Virus is delivered extravascularly by an infected mosquito and infects local muscle cells or Langerhans cells in the skin. Langerhans cells can carry virus to local lymph nodes, where further replication may occur. Virus is delivered to the blood and spreads to target tissues such as skin, joints, and the central nervous system, in addition to distant muscle and lymphatic tissue.

thus to be rapidly removed from the circulation by the highly sulfated glycosaminoglycans in the liver.⁹⁷ Ability to invade target organs depends in part on the duration and height of the viremia but also on other characteristics of the virus important for tissue invasion.⁴⁸⁴

Cell and Tissue Tropism

Viruses that replicate initially in skeletal muscle and lymph nodes near the site of inoculation often spread through the bloodstream to more distant skeletal muscles and other lymphatic tissues. In addition, cardiac myocytes, osteoblasts, brain and spinal cord neurons, and brown fat cells are secondary sites of replication for many alphaviruses in mice^{9,466,535,554} (see Fig. 23.6). Getah virus causes polymyositis.^{325,554,713} EEEV, WEEV, SFV, and SINV cause encephalitis^{44,242,350,466,838}; RRV and CHIKV cause myositis and arthritis^{244,543,907}; and VEEV causes lymphoid depletion and encephalitis.^{260,359,845}

In humans, the skin is a target for alphaviruses that cause a rash,^{230,493} the joints for alphaviruses that cause arthritis,^{229,328,543,772} muscle for alphaviruses that cause myalgia,^{543,590,907} and the nervous system for alphaviruses that cause encephalitis.^{245,760} RRV and SINV have been recovered from skin biopsies.^{423,424,493} RRV replicates in skin basal epidermal and eccrine duct epithelial cells.²³⁰ CHIKV is found in fibroblasts and macrophages.^{328,428} Human synovial cells support RRV infection *in vitro*,³⁷³ and RRV RNA is detected in synovial biopsy specimens.⁷⁴⁷ Joint fluid taken from humans with acute arthritis has

FIGURE 23.7. Schematic diagram of the pathogenesis of alphavirus-induced disease. Viremia may be accompanied by production of interferon, other proinflammatory cytokines, and fever. Virus then spreads through the blood to other target tissues. As the immune response is induced, the viremia is terminated; however, fever is renewed with appearance of a mononuclear inflammatory response in the infected tissue. In infections that lead to rash and arthritis, joint pain usually appears early after infection and prior to the appearance of the rash.

not yielded infectious virus; however, viral antigen and RNA can be detected in macrophages, and these cells support RRV and CHIKV replication *in vitro*.^{328,373,854}

The mechanism by which encephalitic alphaviruses enter the CNS is not entirely clear. Neuroinvasiveness is a component of virulence that varies between viruses and virus strains.¹⁸⁸ Murine studies have shown infection or transport by cerebrovascular endothelial cells,^{396,602,748} infection of choroid plexus epithelial cells,⁴⁶⁶ infection of olfactory neurons,^{133,670,792,837} and transport by peripheral nerves.¹⁵² Once within the CNS, virus can spread cell to cell or through the cerebrospinal fluid (CSF).^{349,584,792} For most encephalitic alphaviruses, the targeted cell within the CNS is the neuron,^{350,466,584} where cellular protein synthesis is suppressed⁸⁰⁴ and damage can be severe and irreversible. In mice that recover from neuronal infection, infectious virus is cleared but viral RNA persists.^{223,446,521,821} SFV, RRV, and VEEV can cause persistent infection of microglial and oligodendroglial cells leading to demyelination.^{94,160,226,715}

Immune Responses

Innate Responses

Early responses to alphavirus infection include production of cytokines and chemokines and activation of NK cells.²⁷¹

Type I (α/β) IFN is induced *in vivo* after many, but not all, alphavirus infections of experimental animals^{242,255,358,721,807} and humans^{328,677,702,853} (see Fig. 23.7). The amount of IFN produced by infected tissues is usually linked to the level of virus replication, and IFN production continues if virus is not cleared.^{91,224,294,328,358,702} IFN rapidly appears in serum, and levels are diminished by splenectomy, suggesting that lymphoid tissue is one important source.^{358,415,416}

Several different cell systems have been used to determine the mechanisms by which alphaviruses induce and control synthesis of IFN in response to infection. Viruses vary in their ability to induce IFN production by different types of cells,^{623,702,721} and the cellular sources of IFN probably differ with time after infection. In tissue culture cell lines, IFN production, shut-off of host protein synthesis, and CPE are controlled either by nsP2 (SINV, SFV) or C (VEEV, EEEV).^{14,81,235,246,247} In these cells, shutoff of host gene expression suppresses antiviral responses.^{14,81,247,894}

The primary source of early IFN *in vivo* may be plasmacytoid DCs for some alphaviruses⁷³⁰ but not for others.⁷⁰² SFV induction of IFN by myeloid DCs requires fusion but not replication, and it is independent of MyD88.³²² For SINV and RRV, N-linked glycans on E2 are important determinants of IFN production by DCs.⁷¹⁹

Induction of IFN requires viral entry and RNA synthesis.^{57,322,881} Data from *ts* mutants suggest that formation of dsRNA is the necessary step in replication for IFN induction. Viruses with mutations in the protease domain of nsP2, which cannot process the nonstructural polyprotein and thus cannot initiate plus-strand RNA synthesis, do not induce IFN.^{298,497} In infected fibroblasts and epithelial cells, dsRNA and higher-ordered RNA structures activate MDA5 and PKR, which are important intracellular sensors of alphavirus infection,⁴⁹ and stimulate phosphorylation of interferon regulatory factor (IRF) 3^{610,706} and formation of the IRF3/CBP/p300 transcriptional activation complex for immediate early IFNs.⁵⁷ This process is independent of mTOR pathway activation.¹⁷⁵ NsP1/nsP2 cleavage affects IRF3 activation and IFN induction by SINV without affecting shutoff of host transcription or translation.¹⁵⁸ Virulent strains of EEEV do not induce IFN after fibroblast infection, whereas attenuated strains do, which is potentially associated with decreased binding to HS and increased infection of lymphoid tissue.^{242,243}

Production of IFN follows the initial release of virus from infected cells by 2 to 3 hours³²⁷ and for some, but not all, alphavirus strains is regulated by nuclear importation of nsP2 and by whether host protein synthesis is shut off before IFN can be synthesized.^{81,92,881} The ability of CHIKV to induce IFN mRNA and protein is cell type dependent.⁷⁰² Primary human monocytes infected by CHIKV produce IFN- α , interleukin (IL)-6, and IL-12³¹⁹; however, similarly infected primary human fibroblasts produce IFN- β mRNA but no protein, because the mRNA is not translated.⁸⁸¹

IFN is an important part of the host response to alphavirus infection, and virus replication is sensitive to its effects.^{12,155,172,441,680,718,753,787,905} Animals can be protected from lethal infection if treated with IFN or IFN inducers before or soon after infection.^{12,358,375,477,714} Animals unable to respond to IFN owing to deletions of the IFN receptor or crucial IFN signaling molecules develop more severe disease than wild-type mice.^{12,95,155,157,210,224,279,679,702,756,880} Furthermore, absence

of an IFN response allows virus replication in cells previously resistant to infection.^{224,678,679,810} IFN appears to act primarily to limit virus replication early, during the time the specific immune response is being induced (see Fig. 23.7). Treatment of cells with IFN inhibits alphavirus replication^{90,172,358,540,551,681}; however, the mechanism by which this occurs, and therefore the IFN-induced host responses important for control of replication, are not known. Attachment and entry are not affected,^{172,641} although later replication steps, including formation of replication complexes, structural protein synthesis, and morphogenesis, are inhibited.^{551,641,787}

In addition to inhibiting host cell protein synthesis, alphaviruses can also interfere with IFN signaling by decreasing Janus kinase (JAK) activation and STAT phosphorylation and nuclear translocation.^{236,733,894} This is a property of either nsP1 or nsP2.^{236,734}

Antiviral proteins PKR and RNase L have a limited role in the IFN-induced antiviral response *in vitro* and *in vivo*.⁶⁸¹ However, activation of PKR improves the stability of IFN mRNA.^{49,706} Interestingly, infected ribonuclease (RNase) L-deficient fibroblasts fail to shut off minus-strand RNA synthesis or form stable replication complexes and establish persistent infection, suggesting a role for RNase L in virus replication.⁶⁹⁸

IFN-induced proteins that can inhibit alphavirus replication include human MxA,⁴³² zinc-finger antiviral protein (ZAP),^{63,292,392,435,488,905} viperin,⁹⁰⁵ the large form of 2',5'-oligoadenylate synthetase,⁸² interferon-stimulated gene (ISG) 20,⁹⁰⁵ and ISG15.^{440,441} Transgenic expression of MxA, a large cytoplasmic guanosine triphosphatase (GTPase), in IFN- α/β receptor-deficient mice results in decreased SFV replication by preventing accumulation of genomic and subgenomic RNA and provides some protection against fatal disease.³¹¹ ZAP is an RNA-binding protein that prevents accumulation of viral RNA by blocking translation of incoming viral genomic RNA.^{63,291} This is accomplished by binding to specific viral mRNA sequences and interaction with the host DEAD box helicase p72 and RNA-processing exosome.^{135,292} ISG15 is an ubiquitin-like molecule that exerts its antiviral effect by conjugating proteins, although the mechanism for suppression of virus replication remains unknown.²⁵¹

Viruses and virus strains vary in their sensitivity to the antiviral activities of IFN, and this may or may not correlate with virulence.^{24,68,174,756,894} Mutations associated with altered sensitivity to IFN have been mapped to the 5' nontranslated region (NTR), nsP1, and nsP2.^{235,667,756,880}

IFN may also contribute to alphavirus-induced disease. Fever during the viremic phase of infection, as is seen with CHIKV and RRV, is probably a response to the IFN induced early after infection (see Fig. 23.7). It has been postulated that the rapidly fatal disease induced by alphaviruses in newborn mice may be owing to the production of large amounts of IFN and pro-inflammatory cytokines.⁸⁰⁷ Acute-phase responses induced by alphaviruses prior to the virus-specific immune response include up-regulation of toll-like receptor expression and increases in tumor necrosis factor (TNF), IL-1, and IL-6, and levels generally correlate with the extent of virus replication.^{278,512,702,807,874} Adult mice deficient in IL-1 β have reduced mortality after CNS infection with a neurovirulent strain of SINV, again suggesting that cytokine effects may contribute to mortality.⁴⁵⁷

Virus-Specific Adaptive Responses

Both cellular and humoral immune responses are induced by infection (see Fig. 23.7). In experimentally infected adult mice, antiviral antibody is usually detected in serum within 3 to 4 days after infection.^{280,592,713} The cellular immune response, manifested by the presence of virus-reactive lymphocytes in draining lymph nodes and blood and the infiltration of mononuclear cells into infected tissues, also appears within 3 to 4 days after infection.^{283,509} These responses appear later (7–10 days after infection) in neonatal mice.⁷²¹ Both appear to play a role in recovery from infection and protection against reinfection.

HUMORAL IMMUNITY

Virus-specific immunoglobulin M (IgM) antibody is detectable very early in human disease, often provides a means for rapid diagnosis of infection, and can persist for many months after recovery.^{69,99,103,112,115,288,424,495,571} Virus-specific immunoglobulin A (IgA) also appears early in infection but declines rapidly.¹¹⁴ Immunoglobulin G (IgG) antibody is present in serum after 7 to 14 days and is maintained at relatively high levels for years.^{101,183,396} Many lines of evidence support the hypothesis that recovery from alphavirus infection depends in large part on the antibody response.^{91,284,906} Rapidity of antibody synthesis is predictive of outcome from encephalitis because patients without evidence of antibody at the time of illness onset are most likely to die.⁹⁹ Antibody can neutralize virus infectivity and promote virus clearance by the reticuloendothelial system in conjunction with complement.³⁵⁶ Appearance of antibody correlates with cessation of viremia (see Fig. 23.7).

The most extensive experimental studies to define the antibody specificity and the mechanisms of antibody-mediated recovery and protection have been done using VEEV, SFV, and SINV infection of mice. Passive transfer of antibody before or after infection is protective. Both neutralizing and nonneutralizing MABs against multiple epitopes on the E1, E2, and E3 glycoproteins can protect against alphavirus challenge and promote recovery.^{65,66,289,343,502,519,597,757,892} There is a correlation of protection with the ability of the MAB to bind to the surface of infected cells, although this is not absolute.⁷⁵⁷ Protection requires intact bivalent antibody but does not require complement.^{323,503} However, virus clearance from blood is delayed in complement-deficient mice.³²⁴

Treatment of immune deficient mice persistently infected with SINV or SFV with antiviral antibody clears infectious virus from the CNS without causing neurologic damage.^{21,448} Clearance of infectious virus is rapid, whereas the decline in viral RNA occurs more slowly.^{448,521} E2-specific MABs can down-regulate intracellular virus replication *in vivo* and *in vitro* by a nonlytic mechanism.⁴⁴⁸ Antibody against an N-terminal peptide of VEEV E2 that is not neutralizing can limit virus replication *in vivo*,³⁴² and a nonneutralizing MAB to SFV E2 can limit virus replication *in vitro*.⁶⁶ Anti-E3 MABs inhibit production of VEEV.⁵⁹⁷ Anti-E1 MABs may also be able to alter intracellular virus replication.¹²⁸

In vitro studies show that the process by which antibody alters intracellular virus replication requires bivalent antibody but does not require the Fc portion of the MAB, complement, or other cells^{448,824}; however, the effects of antibody are amplified by treatment of infected cells with IFN- α .¹⁷² Soon after antibody binding, virion budding from the plasma membrane is inhibited.¹⁷³ *In vivo* studies also show that IFN and antibody act

synergistically to promote recovery, although the mechanisms by which these systems interact have not been identified.^{95,154}

After recovery from encephalitis, viral RNA remains detectable in the CNS for life. Therefore, one consequence of a nonlytic mechanism for clearance of virus from tissue is that the virus genome is not completely eliminated if the originally infected cells survive.^{446,447} This leads to a need for long-term control of virus replication that is accomplished in part by infiltration of antibody-producing B cells into the CNS.^{281,286,521,821}

Antibody also is important for protection from infection.⁵³⁸ Inactivated vaccines protect against EEE, VEE, and WEE.^{636,638} Delivered before or shortly after infection, passive transfer of antibody can protect from acute fatal disease but may predispose to late disease.^{284,399,712}

CELLULAR IMMUNITY

Alphavirus infection induces virus-specific lymphoproliferative, cytokine, and cytotoxic T-cell responses.^{4,283,385,498,531} Cytokines increased in plasma during acute disease include IL-4, IL-6, IL-10, IL-12, IL-13, and IFN- γ .^{328,853} After epidermal virus inoculation, Langerhans cells increase expression of MHC class II antigens and accessory and costimulatory molecules that enhance activation of naive T cells.³⁷⁰ The mononuclear inflammatory process in alphavirus encephalitis is immunologically specific⁵⁰⁹ and includes infiltration of NK cells, CD4⁺ and CD8⁺ T lymphocytes, B cells, and macrophages.^{346,521,529,541} Relative proportions of these mononuclear cells vary with the time after infection.^{346,521,529} T cells play a role in virus clearance and in protection from challenge.^{200,897} Viral RNA levels in the CNS of SINV-infected mice decrease more rapidly when CD8⁺ T cells are present.⁴⁰⁰ Mice lacking the ability to produce antibody can clear infectious virus from some populations of neurons through production of IFN- γ ,^{64,84} and IFN- γ down-regulates SINV replication in mature neurons *in vitro* through a JAK/STAT-dependent mechanism.^{89,90} In animals infected with virulent strains of virus, cellular immune responses contribute to tissue damage and fatal disease.^{273,399,563,669}

Pathologic Changes

Encephalomyelitis

Pathologic changes in the CNS of humans with fatal neurologic disease and mice with experimentally induced encephalomyelitis begin with perivascular infiltration of mononuclear and polymorphonuclear inflammatory cells.^{509,529,577} Adhesion molecules (e.g., ICAM-1, VCAM-1) are up-regulated on endothelial cells and integrins LFA-1 and VLA-4 are important mediators of mononuclear cell entry.^{347,741,750} This phase of infection may include extravasation of red blood cells and endothelial cell swelling and hyperplasia.⁵⁷⁷ Lymphocytes and monocytes move from the perivascular regions to areas of the parenchyma with virus-infected neurons. This inflammatory process is accompanied by gliosis and evidence of inflammatory and glial cell apoptosis.²⁴⁵

Neonatal mice and human infants may die with widespread virus-induced neuronal cell death before the inflammatory process—a manifestation of the cellular immune response—can be initiated.⁵⁵⁵ Immature neurons die by an apoptotic process,⁴⁵² whereas death of mature neurons may be characterized by cytoplasmic swelling, vacuolation, membrane breakdown, and cellular degeneration suggesting necrosis.^{245,307,555} Demyelination has been described as a consequence of EEEV

and WEEV infection in humans^{52,576,577} and of WEEV, RRV, and SFV infection of mice, probably as a result of infection of oligodendrocytes.^{94,532,715}

Reticuloendothelial Infection

The pathology of VEE in horses includes cellular depletion of bone marrow, spleen, and lymph node tissue, and pancreatic necrosis.⁴⁰⁵ Small mammals also develop widespread infection of reticuloendothelial system tissues and may develop ileal necrosis.^{40,266,845} Leukopenia is commonly observed during human infection.⁵³⁴

Arthritis

In CHIKV- and RRV-induced arthritis, there is hyperplasia of the synovial lining, vascular proliferation, and mononuclear cell infiltration.^{328,747} Synovial fluid contains increased protein, CD4⁺ T lymphocytes, activated NK cells and macrophages, and increased levels of monocyte chemotactic protein (MCP)-1/CCL2, IL-6, and IL-8.^{145,229,328} Persistent infection is suggested by the presence of RRV RNA 5 weeks after onset of symptoms⁷⁴⁷ and CHIKV antigen and RNA in synovial macrophages 18 months after acute disease in a patient with chronic arthritis.³²⁸

Rash

Skin biopsies taken from patients with RRV-induced rash show perivascular infiltration of lymphocytes (primarily CD8⁺ T cells) and monocytes without evidence of immune complex deposition.²³⁰

Release and Transmission

A common feature of alphaviruses is their transmission by insects and maintenance in a natural cycle of replication in vertebrate and invertebrate hosts. Arthropod vectors become infected by feeding on a viremic host, are able to transmit the virus 4 to 10 days later (external incubation), and remain persistently infected. Maintenance of this cycle requires an amplifying host that develops a viremia of sufficient magnitude to infect feeding mosquitoes. For many alphaviruses, humans are dead-end hosts unable to infect mosquitoes efficiently. However, human-mosquito-human transmission has been important in epidemics of RRV, o'nyong nyong virus (ONNV), and CHIKV-induced polyarthritis.^{478,689,790} and horse-mosquito-horse transmission is important in epizootics of VEE.^{659,771}

Other modes of transmission are occasionally important. Horses infected with VEEV may shed virus in nasal, eye, and mouth secretions, as well as in urine and milk, resulting in the potential for transmission by the respiratory route.^{118,405} Aerosol transmission of VEEV, CHIKV, and Mayaro virus has occurred in laboratory settings,^{118,378,439,788,799} and aerosolized VEEV has been developed as an agent of biological warfare.⁷²⁸ EEEV persists in the feather follicles of infected pheasants, and transmission among penned pheasants can occur through feather picking and cannibalism.⁶⁹⁷ Person-to-person transmission has not been documented.^{439,659}

Veterinary Correlates and Animal Models

WEEV, EEEV, and VEEV—the first alphaviruses to be cultured—came to the attention of virologists because they caused fatal disease in horses; these viruses remain important equine pathogens.^{182,522,786} EEEV and WEEV cause encephalitis

in horses, whereas VEEV causes severe respiratory disease associated with leukopenia; encephalitis may or may not be present. Getah virus causes an urticarial rash and hind leg edema in horses.⁷¹⁷ WEEV, EEEV, and Highlands J virus (HJV) cause disease in domesticated birds such as chickens, pigeons, pheasants, turkeys, and emus.^{42,167,213,221,476,822,868} The alphaviruses associated with arthritis in humans have not been recognized as important causes of disease in domestic animals.

Good small animal models exist for the encephalitogenic alphaviruses but are less satisfactory for study of the arthritogenic alphaviruses. In mice, alphaviruses generally infect lymphatic tissue, muscle, brown fat, brain, and spinal cord; however, the extent and relative importance of infection at these sites differs among these viruses. For instance, RRV and Getah virus cause primarily myositis, VEEV causes reticuloendothelial infection, and WEEV and EEEV cause encephalitis with neurons as the main target cells.^{9,526,554} In mice infected with relatively avirulent strains of SFV, RRV, and VEEV, the acute encephalitic phase is accompanied by infection of oligodendroglial cells and demyelination.^{94,715} For all alphaviruses, fatal disease in mice is usually associated with CNS infection even if encephalitis is not a manifestation of the human infection. For instance, SINV infection of mice is studied as a model for acute viral encephalitis, although SINV causes arthritis and rash, not encephalitis, in humans.^{349,489,820} Specifics of these animal model systems are discussed with the individual viruses.

Virulence

Virulence is a measure of the ability of the virus to cause fatal disease; for alphaviruses, this usually reflects the severity of neurologic disease. Outcome is influenced by characteristics of both the host and the virus. An early virus determinant of virulence is induction of IFN and susceptibility to IFN-mediated inhibition of replication. Viruses that induce IFN and are susceptible to IFN are generally attenuated.^{12,92,158,235,243,734,756,880} Most alphaviruses show an age-dependent susceptibility to disease.^{9,75,294,554,584,713} Resistance increases with maturation and is associated with decreased virus replication in tissues at the site of virus inoculation and in target tissues (e.g., brain), not with changes in induction of IFN or the ability of infected mice to mount a virus-specific immune response.^{280,287,554} The ability of a virus strain to cause fatal disease or a particular complication of infection also often depends on the genetic background of the host.^{186,759,792,814}; however, the specific genetic determinants of susceptibility are just beginning to be identified.⁷⁹³ Avirulent alphavirus strains may replicate poorly even in newborn animals, whereas virulent strains can usually replicate well and cause disease in adult and newborn animals. The role of the response to IFN is unclear, although older mice increase ISG12 whereas young mice do not.⁴²⁹

For encephalitic alphaviruses, another viral determinant of virulence is their ability to enter the CNS efficiently (neuroinvasiveness). Many alphavirus strains can cause fatal disease after intracerebral or intranasal inoculation but not after subcutaneous or intraperitoneal inoculation. The duration of viremia often correlates with virulence with virulent strains sustaining longer viremias than avirulent strains.^{355,357,360} Peripheral replication, viremia, neuroinvasiveness, and neurotropism (ability to replicate in CNS cells) all contribute to virulence.

The viral determinants of virulence have been most extensively studied in murine models for SINV, SFV, RRV, and

VEEV infections. Viruses with altered virulence have been selected after chemical mutagenesis,^{48,85} by passage in tissue culture,^{58,166,395,783} by passage in mice,^{284,517,783} by isolation of MAb escape mutants⁸⁴² or plaque variants,³⁵⁴ and by manipulation of complementary DNA (cDNA) virus clones.^{166,485,779,815} Nucleotide and amino acid changes affecting virulence have been mapped to the 5' NTR, nsP1, nsP2, nsP3, E1, and E2. Virulence determinants in the glycoproteins map to receptor-binding regions of the E2 A and B domains⁸⁴⁰ (see Fig. 23.4). Specifics are covered in the sections dealing with each of these viruses.

Persistence

There is substantial evidence that alphaviruses can persist after appearance of an immune response and clearance of infectious virus from the circulation and from tissue.⁴⁴⁷ Pathologic examination of CNS tissue from human cases of progressive WEEV months to years after resolution of acute encephalitis has shown an active inflammatory process.^{575,577} Viral RNA and proteins can be detected in the nervous system long after recovery of mice from SINV or SFV-induced encephalitis and for several weeks in the joints of humans with RRV-induced arthritis.^{186,285,396,447,521,747,821} It is postulated that this persistence of RNA is attributable to failure of the virus or the immune system to eliminate the infected cells. Interestingly, passive antibody protection predisposes to persistent infection and the late onset of progressive disease.^{399,712}

Congenital Infection

Alphaviruses can be transmitted transplacentally. This has been documented in mice for RRV, SFV, VEEV, and Getah virus.^{3,30,35,524,755} and in humans for RRV, WEEV, VEEV, and CHIKV.^{6,231,380,723} In mice, the virus infects the placenta, where it is able to persist and spread to the fetus despite the development of maternal antibody. The outcome of fetal infection depends on the timing of infection relative to transfer of maternal antiviral IgG to the fetus. Fetuses are protected if transfer occurs prior to infection; however, transfer of antibody after fetal infection does not mediate recovery.⁵²⁴ In monkeys, congenital infection with VEEV induces malformations of the brain and eye.⁴⁷¹ In humans, no abnormalities were observed in infants infected with RRV at 11 to 19 weeks gestation; however, earlier infection may lead to fetal death.⁶ Epidemics of VEE are associated with increases in spontaneous abortion.^{659,862} No effect on pregnancy outcome was identified during the CHIKV outbreak on Reunion Island.²³¹

PATHOGENESIS AND PATHOLOGY IN MOSQUITOES

The ability of alphaviruses to infect mosquitoes efficiently with spread to and replication in the salivary glands is essential for maintaining the natural cycle of transmission. Not all mosquitoes taking a blood meal from a viremic host will become infected, and not all infected mosquitoes develop the ability to transmit virus. Many alphaviruses preferentially infect a narrow range of mosquito species, and this host specificity plays an important role in determining the geographic distribution of the virus. Even within a species, strains of mosquitoes may vary in

susceptibility to infection. *Ae. albopictus* collected from different geographic regions show differences in susceptibility to infection with CHIKV and in the amount of virus produced after infection.⁷⁸⁹ Field and laboratory populations of *Culex tarsalis* differ in susceptibility to WEEV.³³⁴ Strains of virus also differ in their abilities to infect mosquitoes, and laboratory-adapted strains may establish infection relatively inefficiently.^{557,710,711,831,833}

The extrinsic incubation period—or the time between taking an infected blood meal and ability to transmit infection—depends on the rapidity of virus replication and dissemination to the salivary glands. This period is relatively short (2–7 days) for alphaviruses compared to other arboviruses.⁷¹⁰

Entry and Sites of Primary Replication

Posterior midgut epithelial cells are the initial sites of infection,^{77,558,612,708,864} and infection is facilitated when virus in the serum is concentrated next to these cells as the blood meal clots⁸⁶⁶ (Fig. 23.8). Susceptibility of mosquitoes to alphavirus infection is determined in large part by the ability of the virus to infect midgut epithelial cells.^{334,397,710} Changes both in the virus and vector can affect this interaction.⁸⁸⁹ WEEV rapidly fuses with microvillar membrane preparations from *Cx. tarsalis* mosquitoes, and both WEEV and CHIKV bind better to membranes from susceptible mosquitoes than to membranes from refractory mosquitoes,^{334,546} which is consistent with a role for viral structural proteins as determinants of vector specificity, midgut infection, and dissemination.^{612,813,832,833} The high-affinity laminin receptor A is a receptor for VEEV and SINV on the surface of C6/36 larval *Ae. albopictus* cells,^{474,850} and proteins of 60 and 38 kDa have been identified as putative receptors for CHIKV on brush-border membranes from *Ae. aegypti*.⁵⁴⁶

Host cell membrane cholesterol levels affect the efficiency of alphavirus entry.⁴⁷³ Mosquitoes, like other insects, do not synthesize cholesterol and obtain sterols needed for reproduction and development from dietary blood. Cholesterol-independent

mutants of SFV replicate better than parental SFV in cholesterol-depleted C6/36 cells and in adult *Ae. albopictus* mosquitoes.¹⁶

Replication in midgut epithelial cells is regulated by the RNAi innate antiviral response that is triggered by virus-derived dsRNA and small interfering RNAs.^{109,387,397,559} RNAi affects infection rate of the midgut, intensity of infection, and virus dissemination to secondary tissues and is probably an important determinant of vector competence.^{387,397}

Spread

For the mosquito to become capable of transmission, virus must reach the salivary glands and replicate there (see Fig. 23.8). For most alphaviruses, spread beyond the midgut to other tissues is through the hemolymph.⁷¹⁰ Virus buds primarily from the basolateral surface of the infected midgut epithelial cells and accumulates next to the basal lamina,⁷¹⁰ which is a layered structure composed of mucopolysaccharide that acts as a barrier to hemocoel entry. Dissemination of SINV from the midgut of *Ae. aegypti* mosquitoes depends on expression of endosomal proteins UNC93A and synaptic vesicle-2.¹¹⁰ Replication of ONNV in *Anopheles gambiae* is controlled by expression of heat shock protein cognate 70B.^{731,732} Infected midgut epithelial cells often degenerate and slough 36 to 48 hours after infection; this process may facilitate penetration of the virus into the hemocoel.^{710,865}

Infection of salivary gland acinar cells from the hemolymph requires that the virus again traverse a basal lamina—a process that may depend primarily on hemolymph titer. The fat body is an important site for virus amplification.^{855,864} EEEV infects the midgut, fat body, muscle, and salivary glands without involving the nervous system or the ovarioles,^{708,864} whereas VEEV infects the nervous system⁸⁵⁵ and SINV infects respiratory tissue.⁷³

Once salivary gland infection is established, virus matures by budding into apical cavities or randomly into vesicles basolaterally and apically. This process may be associated with cytopathic changes in the salivary glands.⁵²⁵ The rapidity of virus growth and dissemination to the salivary glands depend on the ambient temperature. Higher temperatures accelerate the transmission cycle in warm months.^{650,816} This can be as short as 2 to 3 days.⁷¹⁰ In general, virus content of an individual mosquito reaches a peak within 4 to 7 days after infection.^{525,710} Some tissues (e.g., fat bodies) produce large amounts of virus, and some (e.g., head ganglia) produce small amounts; others (e.g., ovarioles and Malpighian tubules) remain virus negative.⁵²³

For transovarial transmission to occur, virus must be able to infect oocytes early in development. Failure to infect ovarioles precludes efficient transovarial transmission of most alphaviruses.^{73,176,708,855} However, the presence of RRV and CHIKV in field-caught male mosquitoes suggests that vertical transmission can occur.^{463,639,795} Eggs can also be infected after they have been fertilized. Low levels of vertical transmission have been documented in the laboratory for RRV in *Aedes vigilax*, for SINV in *Aedes australis*, and for CHIKV in *Ae. aegypti*.^{506,589} Vertical transmission in nature has been reported for RRV, SINV, and WEEV.^{176,237,463}

Pathology, Persistence, and Host Response

Although generally considered to be benign for the invertebrate vector, infection may reduce survival and reproductive capacity.^{709,710} The IMD pathway of innate immunity can

FIGURE 23.8. Diagram of mosquito internal anatomy showing the essential sites for alphavirus infection. BL, basal lamina; L, lumen; F, foregut; M, midgut; ME, midgut epithelium; MV, microvilli or brush border; SG, salivary gland. (Adapted from Weaver SC, Scott TW, Lorenz LH, et al. Togavirus-associated pathologic changes in the midgut of a natural mosquito vector. *J Virol* 1988;62:2083–2090.)

be activated by infection to decrease virus replication.⁴¹ Suppression of the RNAi response increases virus replication and mosquito mortality after infection.^{143,387} Mosquitoes remain infected and infectious for life.^{525,710} In the fat body and salivary glands, infection is persistent, although titers decline after the acute phase of infection, decreasing efficiency of transmission.⁷⁰⁸

ALPHAVIRUSES ASSOCIATED PRIMARILY WITH ENCEPHALITIS

Eastern Equine Encephalitis

EEE was first recognized as a disease of horses in the north-eastern United States. In the summer of 1831, more than 75 horses died in three coastal counties of Massachusetts.³⁰⁰ Between 1845 and 1912, epizootics were recorded on Long Island and in North Carolina, New Jersey, Florida, Maryland, and Virginia.^{300,710} The virus responsible for EEE was first isolated in 1933 from the brains of affected horses in New Jersey and Virginia during a widespread outbreak that also involved coastal areas of Delaware and Maryland.⁷⁸⁶ South American eastern equine encephalitis virus (SA-EEEV) was first isolated in 1936 from a horse in Argentina.⁶⁸³ Although human cases were suspected earlier, it was not demonstrated until 1938 when an outbreak in the northeastern United States resulted in 30 cases of fatal encephalitis in children living in the same areas as equine cases. At that time, EEEV was isolated from the CNS of humans,⁸⁶⁷ as well as from pigeons²²¹ and pheasants.⁸⁶⁸

Based on seasonality, location of cases near salt marsh areas, lack of evidence of transmission from horse to horse through contact, short period of equine viremia, and geographic distribution of cases, Ten Broeck et al.⁷⁸⁵ postulated that insects transmitted infection and that birds were likely to be the reservoir host. The first arthropod isolates were actually from chicken mites and lice, which can transmit infection only inefficiently.^{193,710} Transmission of EEEV by *Aedes sollicitans* in the laboratory was accomplished in 1934⁵²⁰; subsequently, multiple *Aedes* species were shown to be competent vectors, although recovery of EEEV from naturally infected mosquitoes did not occur until 1949 with isolates from *Mansonia perturbans* in Georgia³³⁷ and *Culiseta melanura* in Louisiana.¹²⁷ Subsequent work showing the competence of *Cs. melanura* and a consistent association between infected birds and the isolation of virus from this vector has led to the current understanding that *Cs. melanura* is the primary enzootic vector for North American eastern equine encephalitis virus (NA-EEEV) strains.^{27,162,436,710}

Epidemiology

NA-EEEV causes localized outbreaks of equine, pheasant, and human encephalitis in the summer. The virus is enzootic in North America from Maine southward along the Atlantic seaboard and Gulf Coast to Texas, in the Caribbean, and in Central America²⁵⁴ (Fig. 23.9). Inland foci exist in the Great Lakes Region and have extended to South Dakota and Quebec.¹³⁶ The primary enzootic cycle is maintained in shaded swamps where the vector is the ornithophilic mosquito *Cs. melanura*^{27,159,710} (Fig. 23.10). Birds are the primary reservoir host, and many species are susceptible to infection.⁴⁰⁶ The amplifying species for NA-EEEV are wading birds, migratory passerine songbirds, and starlings.^{162,204,414,514} Young birds are probably important for

virus amplification because they are more susceptible to infection, have a prolonged viremia, and are less defensive toward mosquitoes.¹⁶² Multiple mosquito species, such as *Coquillettidia perturbans*, *Ochlerotatus canadensis*, and various *Aedes* species, may serve as bridge vectors for transmission to susceptible mammals.^{27,159,528,710} In temperate areas, the virus is most likely periodically reintroduced by migratory viremic birds or wind-borne infected mosquitoes from subtropical areas of year-round transmission.^{716,861,878,895} Reptiles with viremias that are prolonged and persist through hibernation may maintain the virus focally.⁸⁷⁷ There is no convincing evidence for overwintering in mosquitoes, and ovarioles are not involved after experimental infection of *Cs. melanura* with NA-EEEV.⁷⁰⁸

SA-EEEV is enzootic along the northern and eastern coasts of South America and in the Amazon Basin¹²³ (see Fig. 23.9). In South and Central America, the enzootic cycle is maintained in moist forests where *Culex (Melanoconion)* spp. appear to be the primary vectors.^{710,818} Forest-dwelling rodents, bats, and marsupials are frequently infected and may provide a reservoir; however, these transmission cycles are not well characterized.^{28,710} Infection of reptiles and amphibians is also likely.¹⁵⁹

MORBIDITY AND MORTALITY

NA-EEEV is the most virulent of the encephalitic alphaviruses, with a high mortality owing to encephalitis. Most cases are associated with exposure to wooded areas adjacent to swamps and marshes,⁹⁸ and approximately equal numbers occur in females and males.²¹¹ Children under 10 years of age are most susceptible,²¹¹ with 1 in 8 infections resulting in encephalitis; in adults, 1 in 23 infections result in encephalitis.²⁶¹ The case fatality rate was 60% to 70% in earlier studies and 30% to 50% in more recent studies, with the highest rates in children and the elderly.^{98,125,171,207,211,632} SA-EEEV is much less virulent and causes little human disease despite evidence of human infection in areas of endemic transmission.^{13,123,180,682}

ORIGIN AND SPREAD OF EPIDEMICS

In the northern part of the North American region, human and equine cases of EEE occur between July and October; in the southern region, cases can occur throughout the year.^{125,632} In the Caribbean, outbreaks appear to be linked to virus introduction by southbound migratory songbirds.⁷¹⁰ In North America, human and equine cases usually occur near swamps maintaining enzootic transmission. Outbreaks are initiated when the virus spreads from the enzootic cycle involving ornithophilic mosquitoes into mosquito populations that feed on various hosts (see Fig. 23.10). Multiple species of mosquitoes with catholic feeding habits have been implicated as potential bridge vectors in different regions.^{27,159,528,694,710}

Cases of equine encephalitis are usually the first indication of an outbreak. In the absence of immunization, epizootics appear approximately every 5 to 10 years and are associated with heavy rainfall and warmer water temperatures that increase the populations of enzootic and epizootic mosquito vectors.⁴⁴⁴ Most of the epidemics have occurred in Massachusetts and surrounding states²¹¹; however, the largest recorded outbreak occurred in 1947 in Louisiana and Texas, with 14,344 cases of equine encephalitis and 11,722 horse deaths.¹²⁹ Since 1955, an average of eight cases of EEE have been diagnosed in humans in the United States each year.^{125,126} (Fig. 23.11).

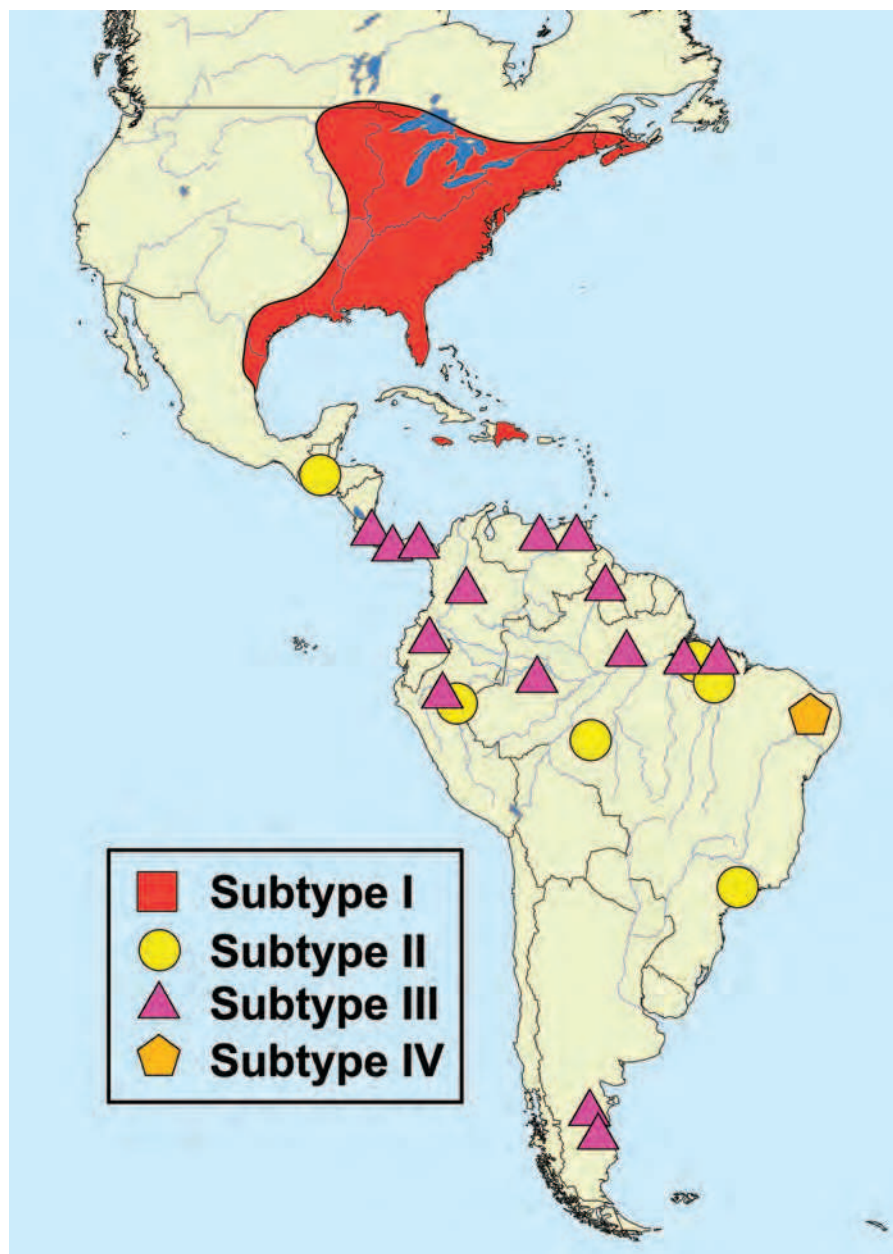

FIGURE 23.9. Geographic distribution of eastern equine encephalitis virus. The map shows the locations for isolation of North American eastern equine encephalitis virus (subtype I) and the three South American eastern equine encephalitis virus lineages (subtypes I, II, and III).⁸⁶¹ (Courtesy of Scott Weaver; from Weaver SC, Powers AM, Brault AC, et al. Molecular epidemiologic studies of veterinary arboviral encephalitides. *Vet J* 1999; 157:123–138.)

MOLECULAR EPIDEMIOLOGY

Antigenic differences between North and South American strains of EEEV have long been recognized,¹¹⁷ and the strains can be distinguished by reactivity with MAbs to the E1 glycoprotein.⁶⁶³ Sequence comparisons indicate that EEEV has evolved independently in North and South America over the past 1,000 years, with 23% to 24% nucleotide and 9% to 11% amino acid sequence divergence.²⁹ There is one lineage of NA-EEEV (lineage I) and three lineages of SA-EEEV: on the coasts of South and Central America (lineage II), in the Amazon basin (lineage III), and in Brazil (lineage IV)^{78,861} (see Fig. 23.9). Isolates of NA-EEEV are highly conserved, differing over a large geographic range by less than 3% in nucleotide sequence consistent with birds as the vertebrate reservoir hosts. The calculated yearly nucleotide substitution rate is 2.7×10^{-4} .^{78,861} The two main lineages of SA-EEEV (II and III)

exhibit 17% to 21% nucleotide divergence and 3% to 5% amino acid divergence and are evolving at a slower rate (1.2×10^{-4} substitutions/nucleotide/year).²⁹ The South American groups are estimated to have diverged 1,000 to 2,000 years ago and appear to be evolving locally, which is consistent with small mammals as the reservoir hosts.^{29,858,861}

Clinical Features and Pathology

Illness caused by infection with NA-EEEV may consist of 1 to 2 weeks of fever, chills, malaise, and myalgias followed by recovery. In cases of encephalitis, these prodromal symptoms are followed by the fulminant onset of increased headache, vomiting, restlessness, irritability, seizures, obtundation, and coma.^{171,207,211} Meningismus is frequent, and focal signs including cranial nerve palsies and hemipareses are not uncommon.^{171,632} Hyponatremia owing to inappropriate secretion of

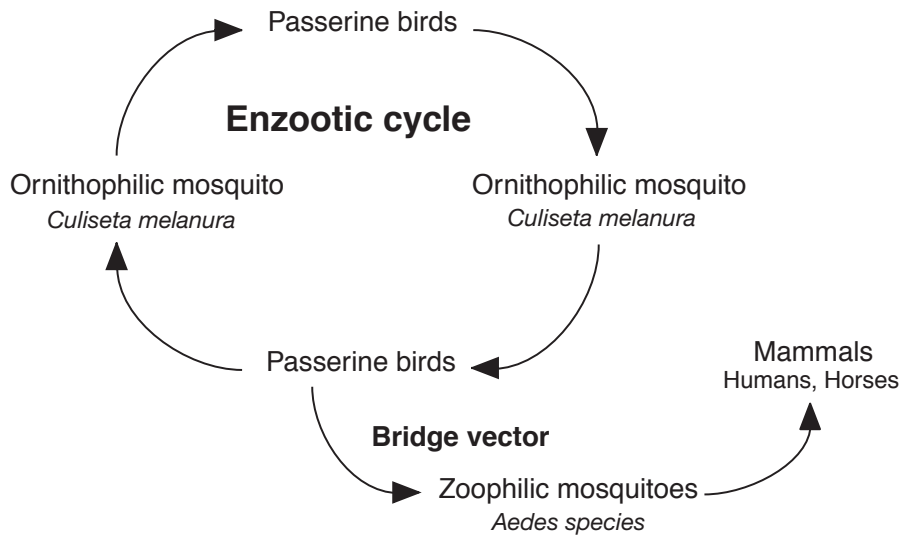

FIGURE 23.10. Enzootic and epidemic/epizootic cycles of eastern equine encephalitis virus as an example of an alphavirus that uses a species of mosquito with different host feeding preferences to bridge from the enzootic avian-ornithophilic mosquito cycle to infect mammals such as humans and horses. Similar mechanisms are operative in transmission of Sindbis virus to humans.

antidiuretic hormone is a common complication, and edema of the face and extremities has been noted.^{171,207} Death typically occurs within 2 to 10 days after onset of encephalitis.

CSF examination shows increased pressure and white cell counts ranging from 10 to 2,000/ μ L. Polymorphonuclear leukocytes are often abundant early in disease, with a shift to mononuclear cells over the first few days of illness.¹⁷¹ The presence of red blood cells or xanthochromia is not uncommon.⁶³² CSF protein levels are increased, whereas glucose is low to normal.^{207,632} Electroencephalographic (EEG) findings are relatively nonspecific, usually showing slowing.¹⁷¹ Computed tomography (CT) scans may be normal or show only edema.^{171,632} Magnetic resonance imaging (MRI) scans are more often abnormal, with focal lesions most commonly observed in the thalamus, basal ganglia, and brain stem.¹⁷¹

Poor outcome is predicted by high CSF white cell count or severe hyponatremia but not by the size of the radiographic lesions.¹⁷¹ Recovery is more likely in individuals who have a long (5–7 day) prodrome and do not develop coma.⁶³² Sequelae, including paralysis, seizures, and mental retardation, are common, with 35% to 80% of survivors, particularly children, having significant long-term neurological impairment.^{171,207,211}

Histopathology on fatal cases demonstrates a diffuse meningoencephalitis with widespread neuronal destruction; perivascular cuffing with polymorphonuclear, as well as mononuclear, leukocytes; and vasculitis with vessel occlusion in the cortex, basal ganglia, and brain stem. The spinal cord is frequently spared.^{207,222,760} Virus antigen is localized to neurons, and neuronal death is marked by cytoplasmic swelling and

FIGURE 23.11. Numbers of human cases of eastern equine encephalitis reported annually in the United States since 1964. (Based on data from the Centers for Disease Control and Prevention.)

nuclear pyknosis.²⁴⁵ Apoptotic glial and inflammatory cells are frequently found in the regions of affected neurons.^{207,245}

Veterinary Correlates, Host Range, and Animal Models

NA-EEEV is an important cause of disease in horses, pheasants, emus, and turkeys and can also cause encephalitis in penguins, sheep, deer, dogs, and pigs.^{53,167,221,293,476,697,780} Horses develop signs of depression, progressive incoordination, seizures, and prostration. The case fatality rate is 80% to 90%. Most survivors are left with neurologic sequelae.⁷¹⁰ Birds vary in their susceptibility—some species develop disease, whereas many others show no morbidity or mortality despite a prolonged viremia.^{406,476} Chickens, turkeys, emus, and whooping cranes often develop fatal viscerotropic disease with multifocal necrosis in the heart, kidney, and pancreas and lymphoid depletion in thymus, spleen, and bursa.^{167,293,822} Pheasants develop encephalitis with 50% to 70% mortality, whereas penguins develop nonfatal encephalitis.^{476,697}

Laboratory studies of macaques, marmosets, mice, guinea pigs, and hamsters generally confirm the neurovirulence of NA-EEEV for mammals.^{222,466,592,670,760,786,838,893} NA-EEEV can initiate CNS infection in experimental animals by infecting choroid plexus epithelial cells or olfactory neurons.^{466,670} Peripheral replication is in fibroblasts, skeletal muscle, and osteoblasts.⁸³⁸ Macaques and marmosets develop encephalitis, whereas New World *Aotus* monkeys develop viremia without evidence of disease.²⁰² Young mice show extensive neuronal damage and rapid death.⁸³⁸ Older mice are relatively resistant to peripheral inoculation; however, after intracerebral inoculation, they develop seizures and die rapidly.^{242,466} Guinea pigs develop encephalitis after aerosol exposure to NA-EEEV with neuronal death, inflammation, and vasculitis.⁶⁷⁰ Hamsters develop a biphasic fatal illness with hepatitis and lymphatic organ infection followed by encephalitis characterized by extensive vasculitis and microhemorrhages.⁵⁹²

Virulence

NA-EEEV is more virulent than SA-EEEV in humans and experimental animals.^{12,123,710} Construction and testing of chimeric viruses in mice indicate that both structural and nsPs contribute to virulence.¹⁰ Viruses with a temperature-sensitive, small plaque phenotype, and decreased virulence for mice and hamsters have been selected after chemical mutagenesis.⁸⁵ One determinant of the neurovirulence of NA-EEEV is the ability to bind HS. Increased HS binding is associated with decreased tropism for lymphoid tissue, decreased production of IFN, and increased replication in the CNS.²⁴²

Diagnosis, Treatment, and Prevention

Diagnosis is based on virus isolation or detection of RNA or antibody. Virus can be isolated from CSF, blood, or CNS tissue by inoculation into newborn mice or onto various tissue culture cells. Detection and identification of virus in field and clinical samples can also be accomplished through various nucleic acid amplification assays.⁴³⁰ Antibody is usually measured by enzyme immunoassay (EIA), with detection of IgM in serum and CSF particularly useful.^{99,100} No specific therapies have been developed for treatment of EEE; thus, treatment is supportive.⁶⁴⁵

Infection in mosquito populations can be monitored by virus isolation, by nucleic acid amplification, or by seroconver-

sion of sentinel pheasants or chickens. This information can be used to guide insecticide spraying to reduce adult and larval mosquito populations and prevent human cases. A formalin-inactivated vaccine based on an NA-EEEV strain (PE-6) is available for horses and emus and for investigational use in humans to protect laboratory workers. This vaccine does not induce significant neutralizing or anti-E2 antibody to SA-EEEV.⁷⁶⁷

Western Equine Encephalitis

Epizootics of viral encephalitis in horses were described in 1908 in Argentina. In 1912, 25,000 horses were estimated to have died in the central plains of the United States.⁶⁸³ In the summer of 1930, a similar epizootic occurred in the San Joaquin Valley of California, causing an estimated 6,000 cases of equine encephalitis. During this outbreak, WEEV was isolated from the brains of two affected horses by intraocular inoculation of another horse, and this virus was subsequently used to infect other animals.⁵²² WEEV was suspected at that time to be a cause of human encephalitis. In 1938, WEEV was recovered from the brain of a child with fatal encephalitis.³³⁵

Mosquitoes were implicated in disease transmission when it was demonstrated that horses developed a viremia³³⁶ and that experimentally infected *Ae. aegypti* mosquitoes were capable of transmitting the virus to horses.³⁸⁸ However, it was not until the summer of 1941 during a widespread epidemic in the northern plains of the United States and Canada that the virus was isolated from naturally infected *Cx. tarsalis* mosquitoes.²⁹⁹ Subsequently, WEEV was isolated from *Cx. tarsalis* in other epizootic sites and recognized to be the principal vector.

Other New World Western Equine Encephalitis Complex Viruses

The WEE complex in the New World includes three viruses in addition to WEEV: Highlands J (HJ), Buggy Creek, and Aura viruses.¹⁰² These viruses have different ecological niches and vary in virulence. Only WEEV is recognized to cause human disease.⁹⁸ Viruses in the WEE complex found in the Old World (e.g., SINV and Whataroa virus) are discussed in the later Sindbis section. WEEV, HJV, and Fort Morgan virus all belong to the lineage that diverged since recombination between a Sindbis-like virus and an EEE-like virus.²⁹⁷ Aura virus is a “pre-recombinant” virus (see Fig. 23.5).

HIGHLANDS J

WEEV-like viruses were first isolated in the eastern part of the United States in 1952. In 1960, the prototype HJV was isolated from a blue jay in Florida.³¹⁷ HJV is enzootic on the U.S. East Coast and is maintained in a cycle similar to that of EEEV, with *Cs. melanura* the primary vector and migrating birds the primary reservoir. All alphaviruses in the WEEV complex isolated in the eastern United States are strains of HJV.³⁰⁹ Rates of divergence of WEEV and HJV of 0.1% to 0.2% per year have been estimated.¹⁴⁶ HJV can occasionally cause encephalitis in horses³⁸¹ and is a recognized pathogen for various avian species, including turkeys, pheasants, partridges, ducks, emus, hawks, and whooping cranes.^{19,213,293,861}

FORT MORGAN, BUGGY CREEK, AND STONE LAKES

Fort Morgan virus and its close relative Buggy Creek virus were originally isolated from swallows and sparrows in eastern Colorado¹⁰⁵ and Oklahoma.³³² These viruses exist as two lineages

found primarily in the western plains of North America^{591,607} and are transmitted to cliff swallows and sparrows by cimicid swallow nest bugs (*Oeciacus vicarius*).⁸⁶ Neither virus is recognized as a pathogen for humans; however, the viruses cause encephalitis in nestling house sparrows.⁵⁷⁸ Recently, a third related virus, Stone Lakes virus, was isolated from swallow bugs in California.⁷⁶

AURA

Aura virus was isolated in 1959 in Brazil from *Culex (Melanoconion)* spp. collected near the Aura River and later from *Aedes serratus* in Brazil and Argentina.¹²¹ This virus is likely to be related to the “Sindbis-like” virus that recombined with EEEV to produce WEEV.⁶⁷⁴ It has not been linked to human disease and is relatively nonpathogenic for mice.

Epidemiology

WEEV is widely distributed in the western plains and valleys of the United States and Canada and in South America. In North America, WEEV is maintained in an endemic cycle involving domestic and passerine birds (particularly finches and sparrows) and *Cx. tarsalis*, a mosquito well adapted to irrigated agricultural areas.⁹⁸ Occasional isolations have been made from *Aedes melanimon* and *Aedes dorsalis*, which also are competent vectors. There is evidence for a transmission cycle involving *Ae. melanimon* and the black-tailed jackrabbit^{98,302} in addition to the *Cx. tarsalis*–avian cycle. Increased transmission is associated with greater abundance of *Cx. tarsalis*.⁴⁶ Serosurveys and virus isolations provide evidence of natural infection in chickens, pheasants, rodents, rabbits, ungulates, tortoises, and snakes. In some areas of South America, most mosquitoes from which WEEV has been isolated feed primarily on mammals and antibodies are common in small mammals including rats and rabbits, whereas in other areas, antibodies are found primarily in birds.^{726,861} A recent survey of horses in the Pantanal region of Brazil found 36% seropositivity for WEEV.⁶⁰³ Interseasonal persistence can occur in saltwater marshes, perhaps by overwintering in adults.^{648,649}

MORBIDITY AND MORTALITY

WEEV in the western United States has caused epidemics of encephalitis in humans, horses, and emus; however, the case fatality rate of 10% for humans, 20% to 40% for horses, and 10% for emus is lower than for NA-EEEV. In older children and adults, males are two to three times more likely to develop disease than females.⁴⁷² The estimated case to infection ratio is 1:58 in children younger than 5 years and 1:1150 in adults.⁹⁸ Clinically apparent disease is most common in the very young and those older than 50 years.⁴⁷² Severe disease, seizures, fatal encephalitis, and significant sequelae are more likely to occur in infants and in young children.^{194,412} The overall case fatality rate is 3% but rises to 8% in those older than 50 years.⁴⁷² Accidental infections involving aerosolized virus in the laboratory have been reported²²² and have led WEEV to be regarded as a potential bioterrorist threat.⁷²⁸

The rare occurrence of significant human disease during equine outbreaks of WEE in South America may be related to the feeding habits of the vector or to a lower virulence of South American strains for humans and horses.^{169,683}

ORIGIN AND SPREAD OF EPIDEMICS

There have been large, often widespread epidemics of equine encephalitis occurring from mid June to late September in North America with significant spillover into the human population. These outbreaks correlated with regional increases in the population densities of *Cx. tarsalis*.⁵⁸⁷ Major epizootics occurred every 2 to 3 years in the United States from 1931 to 1952. In 1941, more than 3,400 human WEE cases were reported in the plains of the western United States and Canada, with attack rates of up to 167 cases/100,000 population.⁹⁸ During the 1952 epidemic in California's Central Valley, attack rates were 36 cases/100,000 humans and 1120/100,000 equids.⁹⁸ Seroprevalence in humans was 34% in rural areas of California endemic for WEEV in 1960²³² but only 1.3% to 2.6% in similar areas from 1993 to 1995.⁶⁴⁶ Human cases of WEE have steadily declined to fewer than one to two human cases/year over the past 20 years (Fig. 23.12). This decline is

FIGURE 23.12. Numbers of human cases of western equine encephalitis reported annually in the United States since 1964. (Based on data from the Centers for Disease Control and Prevention.)

not understood but does not appear to be owing to a decrease in virus virulence or change in vector competence.^{218,647,900}

Studies of differential virulence of epizootic and enzootic strains in South America first suggested that epizootic strains arise from nonpathogenic enzootic strains.⁶¹ Sequence analysis of the viruses found at the initial focus of the 1982 WEE epizootic in Argentina indicated that the enzootic virus was the source of a virulent variant, which emerged by mutation or selection to cause the epizootic. The epizootic vector in South America is *Aedes albifasciatus*, and rabbits may serve as an amplifying host.⁸⁶¹

MOLECULAR EPIDEMIOLOGY

WEEV has four major lineages—two in South America and two widely distributed in North and South America and the Caribbean.^{859,861} One was isolated during the 1982–1983 epizootic in Argentina, a second is related to the McMillan strain found in North and South America and Cuba from 1930 to 1972, a third was found in the same regions from 1964 to 1993, and a fourth was found in Brazil and Argentina. Within California, separately evolving lineages have been identified in the Central Valley and the southern part of the state.⁴¹⁹

Clinical Features and Pathology

WEEV causes encephalitis with signs and symptoms similar to those of EEE. Transmission can occur by aerosols as well as by mosquitoes.⁶⁴² There is a 3- to 5-day prodrome of fever and headache that may progress to restlessness, tremor, irritability, nuchal rigidity, photophobia, altered mental status, and paralysis.^{214,412,516} Infants often present with rigidity, seizures, and a bulging fontanel.^{214,516} Transplacental transmission results in perinatal infection manifesting within the first week of life as fever, failure to feed, and seizures.^{516,723} CSF pleocytosis is typical with 100 to 1,500 cells/ μ L. Neutrophils are present early in disease and mononuclear cells later.⁵¹⁶ In infants less than 1 year of age, approximately 60% of survivors have brain damage, and in some the disease is progressive.^{516,576} Common problems are cognitive disabilities associated with quadriplegia, spasticity, recurring seizures, cortical atrophy, ventricular dilation, and intracranial calcification.^{194,214,576,751} In older individuals, recovery is typically rapid, with remission of signs and symptoms within 5 to 10 days, and sequelae are less common (5%).²¹⁴ Age-dependent susceptibility is likely related to the maturation-dependent ability of neurons to respond to IFN and limit virus replication.¹²⁰

Pathology of acute cases of WEE shows leptomeningitis and perivascular cuffing with neutrophils in the earliest cases and lymphocytes, plasma cells, and macrophages at later times. In areas of neuronal degeneration, there is inflammation accompanied by endothelial hyperplasia, petechial hemorrhages, and glial nodules. Lesions are found primarily in the basal ganglia, brain stem, cerebellum, cerebral cortex, and spinal cord, with areas of focal necrosis and demyelination in the subcortical white matter and basal ganglia.^{214,576,577}

Occasionally in infants and children, there is pathologic evidence of progressive disease consistent with persistent infection.^{516,576,577} Individuals surviving months to years after onset of encephalitis (often with progressive disease) may have cystic lesions, gliosis, and demyelination with areas of active mononuclear inflammation.^{576,577}

Veterinary Correlates, Host Range, and Animal Models

WEE was first recognized as a neurologic disease of equids characterized by fever, incoordination, drowsiness, and anorexia leading to prostration, coma, and death in approximately 40% of affected animals.¹⁸² Emus also develop symptomatic, often fatal disease characterized by ataxia, paralysis, and tremors.⁴² As a part of its enzootic cycle, WEEV infects sparrows, finches, blackbirds, mourning doves, pheasants, cowbirds, swallows, and chickens. The virus can cause fatal disease in sparrows, whereas chickens, which are often used as sentinels, develop asymptomatic infection.⁶⁵¹

Experimentally infected newborn mice die within 48 hours after infection with involvement of skeletal muscle, cartilage, and bone marrow. In weanling mice, the brain, heart, lung, and brown fat appear to be the primary target tissues.⁹ After intracerebral inoculation, there is infection of the choroid plexus and ependyma with spread to neurons and glial cells in the brain, cerebellum, and brain stem and to motor neurons in the spinal cord.⁴⁶⁶ After peripheral inoculation, WEEV replicates in skeletal and cardiac muscle cells, causes a necrotizing myocarditis, and occasionally spreads to the CNS.^{466,535} Hamsters are more susceptible to WEEV-induced disease than mice, with high mortality owing to encephalitis after intranasal or intraperitoneal inoculation.³⁷⁵ Neurons are infected, and neuropathologic changes include perivascular inflammation, microcavitation, and astrocytic hypertrophy.⁹⁰⁹ Cynomolgus and rhesus macaques are susceptible to intranasal, aerosol, and intracerebral infection and develop dose-dependent signs of encephalitis with fever, tremors, and altered consciousness. Pathology shows encephalitis with infection of neurons accompanied by mononuclear inflammation.^{642,893}

Virulence

Variants of WEEV with decreased pathogenicity for mice and hamsters (e.g., B628 clone 15) have been selected by passage on CEF cells.⁹⁰⁹ Large plaque strains tend to be more virulent than small plaque strains.³⁵⁴ Epizootic strains appear to be optimized for viremia and neuroinvasiveness and are generally more virulent for mice and guinea pigs than are enzootic strains.^{61,62,303} North American isolates vary substantially in their virulence for mice but are generally more virulent than South American strains.^{218,469,561} The molecular bases for any of these differences have not been defined; however, preliminary sequencing suggests that structural region genes are important determinants of virulence.⁵⁶¹

Diagnosis, Treatment, and Prevention

Diagnosis can be made by detection of WEEV-specific IgM in serum, by isolation of virus in mice or cultured cells, or by nucleic acid amplification.^{99,430} Small molecule screening has identified potential lead compounds that inhibit WEEV replication and are partially protective in mice.^{377,604} An inactivated vaccine is available for horses and as an experimental preparation for laboratory workers.⁶³⁸ Preclinical studies of approaches to protection include activation of innate immunity,⁴⁷⁰ DNA virus vectors expressing IFN or viral proteins, and chimeric alphaviruses.^{33,45,248,560,774,890,891}

Venezuelan Equine Encephalitis

Equine disease was recognized in South America in the 1920s. In 1936, a virus (VEEV) was isolated from the brains of encephalitic horses during an outbreak of equine encephalitis that spread from the central river valleys of Colombia into the Guajira region of Venezuela. This virus was antigenically distinct from the viruses causing equine encephalitis in the eastern and western portions of North America (EEEV and WEEV) and became the third encephalitic alphavirus identified in the Americas.^{56,420} Between 1943 and 1963, many VEEV-related viruses, including the prototypic Trinidad donkey (TrD) strain,⁶³⁷ were isolated in South America, Central America, and southern regions of the United States.¹¹ The first reported human cases of VEE were in laboratory workers^{118,439}; subsequently, human disease was documented in the general population during equine outbreaks, and virus was isolated from ill humans.^{637,692,857}

Studies in Central America during this period indicated an enzootic cycle involving *Culex (Melanoconion)* spp. mosquitoes and rodents.²³⁹ In 1969, an epizootic/epidemic of VEE appeared and spread from Peru through Central America and into Texas, causing human disease and a high mortality in horses.¹¹ Virus isolations during the epizootic were primarily from *Psorophora confinnis* and *Ae. sollicitans* mosquitoes and from horses, suggesting that the epizootic and enzootic transmission cycles differed.^{404,771}

Venezuelan Equine Encephalitis Complex Viruses

Using a short incubation HI test, isolates of viruses related to VEEV were originally classified into subtypes I through IV:

VEE (I), Everglades (EVE, II), Mucambo (MUC, III), and Pixuna (PIX, IV).⁸⁹⁶ When Cabassou (CAB) and AG80–663 (Rio Negro [RN]) viruses were isolated and shown to be within the VEEV antigenic complex, they became subtypes V and VI.^{104,181} The VEE subtype I viruses have been further subdivided serologically into IAB, IC, ID, IE, and IF (Mosso das Pedras)^{104,857,896} and the MUC subtype III viruses into IIIA, IIIB (Tonate [TON]/Bijou Bridge), IIIC, and IIID.^{403,857} Analysis of the phylogenetic relationships of the VEE complex viruses gained from sequencing has led to a recognition of eight species within the VEEV complex^{402,518,629} (Fig. 23.13; see Table 23.1).

EVERGLADES

EVE virus (serotype II) was first recognized in southern Florida in the 1960s in persons living near Everglades National Park. Transmission is widespread in Florida with *Culex (Melanoconion) cedecei* as the primary vector and cotton rats (*Sigmodon hispidus*) the main vertebrate reservoir.^{148,863} Disease in humans is usually mild.¹⁹⁸

MUCAMBO

MUC virus (serotype IIIA) was first isolated (BeAn 8) from a Brazilian monkey in 1954.¹²³ Three clades have been identified, with temporally defined clades 1 and 2 from Trinidad and clade 3 from Brazil.^{38,39} The virus causes fatal disease in newborn mice and in adult mice after intracerebral, but not peripheral, inoculation. Experimentally inoculated guinea pigs and horses survive infection.⁷²⁵

TONATE

TON virus (serotype IIIB) was first isolated in 1973 from a bird (*Psarocolius decumanus*) captured in French Guiana¹⁸¹ and

FIGURE 23.13. Venezuelan equine encephalitis virus phylogenetic tree showing relationships of epizootic (colored red and orange) and enzootic/endemic strains (colored green). Strains are abbreviated with country followed by year of collection. The tree was generated using 817 nucleotide sequences from the PE2 envelope glycoprotein gene using maximum likelihood methods. (Courtesy of Scott Weaver.)

subsequently from *Culex portesi*.⁵⁹⁵ TON virus (Bijou Bridge) has also been recovered from cliff swallow bugs and birds in North America.⁵³⁶ Human seropositivity is 11.9% in French Guiana, with the highest rates in savannah areas.⁷⁷⁶ Infection is most often associated with a mild dengue-like illness but has caused fatal encephalitis in a young child.³³¹

PIXUNA

PIX virus (serotype IV) was first isolated (BeAr 35645) from *Anopheles (Stethomyia) nimbus* mosquitoes in Belem, Brazil, in 1961⁷²⁵ and has also been identified in Argentina.^{613,614} There is no evidence that it causes disease in humans or horses.

CABASSOU

CAB virus (serotype V) was first isolated (CaAr 508) from mosquitoes in French Guiana in 1974.¹⁸¹ This virus is not neurovirulent for adult mice or guinea pigs.

RIO NEGRO

RN virus (serotype VI) was first isolated (AG80–663) from *Culex (Melanoconion) delpontei* near the Rio Negro in Argentina in 1980.¹⁰⁴ The virus circulates in neotropical regions of Argentina,^{527,613,614} where it has caused outbreaks of acute febrile illness.¹⁵¹ Suckling mice die within 2 to 3 days; however, adult mice and guinea pigs survive infection.¹⁰⁴

Epidemiology

Enzootic VEE complex viruses are involved in perennially active transmission cycles in subtropical and tropical areas of the Americas (e.g., EVE in Florida; VEE ID and IE in Central America; Mosso das Pedras, MUC, PIX, CAB, and RN in South America). In enzootic areas, mosquito isolates are primarily from *Culex (Melanoconion)* spp. mosquitoes that live in tropical and subtropical swamps throughout the Americas, breed near aquatic plants, and feed at dawn and dusk on various rodents, birds, and other vertebrates.^{11,212,239,272} Wild birds are susceptible to infection; however, mammals, such as cotton rats, spiny rats, bats, and opossums, are the most likely reservoir hosts, as determined by virus isolation, levels of viremia, serology, and resistance to disease.^{47,113,205,272,857}

MORBIDITY AND MORTALITY

Clinically evident human infection can occur with enzootic, as well as epizootic, VEE complex viruses.^{11,198,331,776,857} Humans living in areas of enzootic transmission have a high prevalence of antibody owing to infection associated mostly with undiagnosed mild febrile illnesses, often assumed to be dengue.^{11,205,272,701,776} During epizootics, human attack rates vary widely.⁶⁵⁹ The apparent to inapparent infection ratio is estimated at 1:11.⁷² All ages and both sexes are equally susceptible to infection; however, disease manifestations vary with age.⁶⁵⁹ Individuals younger than 15 years are more likely to develop fulminant disease with reticuloendothelial infection, lymphoid depletion, and encephalitis. In older children and young adults, a relatively benign influenza-like illness is most common.¹⁹⁸ Individuals older than 50 years are prone to develop encephalitis, although most recover.¹⁹⁸ The incidence of encephalitis in clinically ill humans is generally less than 5% and the mortality less than 1%.⁶⁵⁹ Essentially all deaths occur in children.

ORIGIN AND SPREAD OF EPIDEMICS

VEE epizootics/epidemics have occurred at approximately 10- to 20-year intervals in cattle ranching areas of Venezuela,

Colombia, Peru, and Ecuador when heavy rainfall leads to increased populations of epizootic mosquito vectors and herd immunity decreases.⁶⁵⁹ Formalinized vaccines containing residual live virus were probably responsible for initiating the IAB outbreaks in South America that spread to Central America and Texas between 1969 and 1972⁴⁰⁴ and in Peru in 1973.^{629,860} Viruses causing epizootics are subtype IAB, IC, or IE, whereas enzootic viruses are ID, IE, or IF. During 1995, a major VEE IC outbreak occurred in coastal areas of Venezuela and Colombia that caused disease in 75,000 to 100,000 people. This region had experienced a similar outbreak in 1962–1964. A ID virus obtained from a mosquito pool collected in Venezuela in 1983, when there was no epidemic activity, was similar in sequence and indicated that the epizootic IC virus was not maintained in a separate cycle but rather evolved by mutation from an enzootic ID virus.^{629,657,862} (Figs. 23.13 and 23.14). A similar process accounted for the emergence of a IC virus in 1992–1993 from a ID virus.²³ Epizootic potential is correlated with positive-charge mutations in E2 that increase the level of viremia in equines and may also increase infectivity for the mosquito vector *Ochlerotatus taeniorhynchus*.^{23,80,275} During epizootics, horses are an important amplifying species, and susceptible equines provide a means for virus spread.⁷⁷¹

Detailed phylogenetic studies have delineated six major lineages of enzootic VEEV, including five subtype ID strains and the subtype IE lineage (see Fig. 23.13). All epizootic strains from major outbreaks fall into a clade nested within one of these lineages.⁸⁵⁷ Enzootic IE viruses were the source of epizootic IE strains in two recent equine epizootics in Mexico.⁵⁷⁹ Interestingly, these epizootic IE strains cause encephalitis in horses with little viremia.^{262,685}

During outbreaks, virus has been isolated from several species of mosquitoes. Those most incriminated as VEEV vectors include *Ochlerotatus sollicitans*, *Oc. taeniorhynchus*, *Psorophora columbiana*, and *P. confinnis*.^{771,857} After an epizootic, IC viruses may persist in a natural cycle and serve as a source for subsequent smaller outbreaks.⁵⁶⁶

MOLECULAR EPIDEMIOLOGY

Sequence analysis of the VEE complex viruses shows the greatest divergence for the E2 glycoprotein and the C-terminal region of nsP3.^{518,629} Five enzootic subtype ID lineages have been identified: Colombia and coastal Ecuador, Panama, Colombia, western Venezuela, and northern Peru (see Fig. 23.13). All epizootic IAB and IC strains are related to ID strains from Colombia, Venezuela, and Peru.^{629,857} Three distinct geographically separate IE lineages have also been recognized: northwestern Panama, Pacific coast (Mexico and Guatemala), and Gulf/Caribbean coast (Mexico and Belize).⁵⁸⁰

Clinical Features and Pathology

Infection with enzootic, as well as epizootic, strains of VEEV can cause significant human disease, with the most common signs and symptoms being fever, headache, tremors, prostration, nausea, and vomiting that last from 3 to 4 days.¹¹ Accidental laboratory aerosol infections of young adults with epizootic strains of VEEV caused a febrile illness with the abrupt onset of chills, headache, myalgia, somnolence, vomiting, diarrhea, and pharyngitis 2 to 5 days after exposure without evidence of encephalitis.^{118,198,439} Natural epidemic human infection was first described in 1952 in Colombia and subsequently

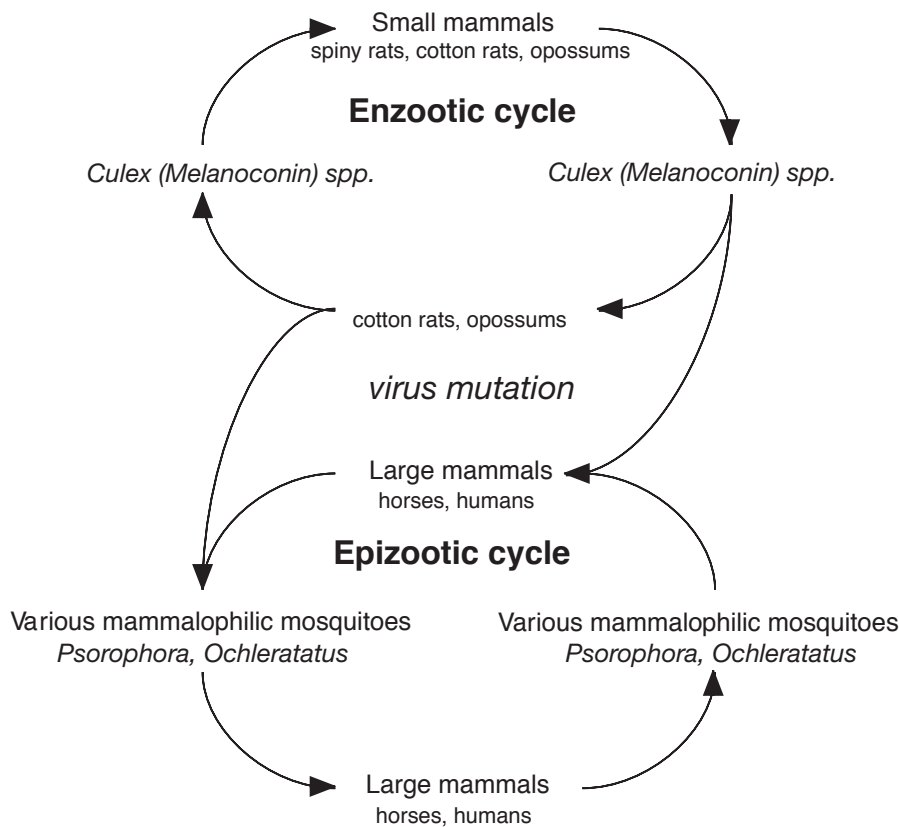

FIGURE 23.14. Enzootic and epidemic/epizootic cycles of Venezuelan equine encephalitis virus as an example of an alphavirus for which the epizootic strain arises by mutation from the enzootic virus. Similar mechanisms may be operative in transmission of epidemic western equine encephalitis virus.

in Venezuela and Panama during the 1962–1964 outbreak that resulted in 32,000 human cases and 190 deaths.^{198,368} The 1995 outbreak in Colombia caused an estimated 75,000 human cases—3,000 with neurologic complications and 300 deaths.^{659,862} The case fatality rate is 0.7% to 1%. Neurologic disease tends to appear 4 to 10 days after onset of illness, with headache and vomiting the most common initial symptoms. Specific neurologic signs include focal or generalized seizures, paresis, behavioral changes, and stupor or coma.^{659,862} Children recovering from encephalitis may be left with neurological deficits, particularly seizure disorders.⁴⁴² Fetal abnormalities, spontaneous abortions, and stillbirths may occur with infection during pregnancy.^{659,862}

Laboratory studies often show lymphopenia. Pathology on fatal cases has shown myocarditis, focal centrilobular hepatic necrosis and inflammation, generalized lymphoid depletion, cerebral edema, and vasculitis.³⁶⁸ Congenitally infected infants show severe neurologic damage with widespread necrosis, hemorrhage, and hypoplasia resulting—in the most severe cases—in hydranencephaly.⁸⁷⁰

Veterinary Correlates, Host Range, and Animal Models

Enzootic strains of the VEE complex can infect horses, although these infections are asymptomatic or cause short-term fever, low-level viremia, and little clinical illness and may immunize horses against infection with epizootic strains (IAB, IC, and IE).^{316,857} Equine disease induced by epizootic strains is characterized by fever, depression, and diarrhea leading to death 6 to 8 days after infection. Viremia persists until death, with titers up to 10^8 infectious units/mL blood. Virus

can also be recovered from eye washings, nasal washings, and urine. Leukopenia coincides with the viremia and is progressive in fatal cases. In animals that recover, antibody appears approximately 7 days after infection.⁴⁰⁵ Pathology on fatal cases shows pancreatic necrosis and cellular depletion in bone marrow, lymph nodes, and spleen. The brains of horses with signs of neurologic disease show swollen cerebrovascular endothelial cells, edema, extravasation of blood, and leukocytic infiltration into the perivenular spaces.^{260,405}

Infection of macaques by aerosol or subcutaneous inoculation with enzootic and epizootic strains of virus elicits a biphasic febrile response—the first phase is coincident with the viremia and the second phase with termination of viremia—that is, the appearance of the immune response.^{260,534,644} (see Fig. 23.7). Leukopenia is common. Symptoms are usually mild, consisting of anorexia, loose stools, and irritability, and occasionally loss of balance, tremor, or myoclonus.^{534,760} Examination of tissues shows lymphocyte depletion early, mild hepatitis, myocarditis, and encephalitis. Lesions in the brain are found primarily in the olfactory cortex and basal ganglia and consist of lymphocytic perivascular cuffing and glial nodules.²⁶⁰

Experimental infection of small laboratory animals with VEEV produces various disease patterns. After subcutaneous inoculation of guinea pigs, rabbits, or hamsters with virulent strains of VEEV, there is a viremia. Virus replicates in bone marrow, lymph nodes, spleen, and brain, with rapid destruction of myeloid and lymphoid cells in lymph nodes, spleen, thymus, intestinal and conjunctival lymphoid tissue, liver, and bone marrow; damage to the intestinal wall and pancreas; cerebral hemorrhage; and neuronal cell death.^{260,359,845} Death occurs 2 to 4 days after infection and may be associated with

ileal necrosis, bacteremia, and endotoxemia.²⁶⁶ EVE, MUC, and PIX viruses are progressively less virulent.³⁵⁹

In addition to myeloid and lymphoid necrosis, susceptible strains of mice develop encephalomyelitis leading to death in 6 to 9 days after infection with the TC-83 vaccine strain, as well as wild-type strains of VEEV.^{260,376,475} After subcutaneous inoculation, virus replicates first in DCs or Langerhans cells, which migrate to the draining lymph node where virus is amplified⁴⁸⁷ (see Fig. 23.6). Virus enters the CNS by the olfactory route after respiratory or peripheral inoculation. Initial infection is of olfactory epithelium, with spread to olfactory neurons and then caudally to all regions of the brain, causing encephalitis and neuronal apoptosis.^{133,351,759,760,837} Virus also infects the pancreas, liver, and teeth. Fatal disease has an immunopathologic component that depends on the strain of mouse infected.^{132,475,760} There can also be transplacental transmission of infection.⁷⁵⁵

Virulence

Comparative studies of the virulent TrD and avirulent TC-83 strains of the IAB serotype and construction of recombinant viruses have led to identification of the 5' NTR (nt 3) and the E2 glycoprotein (residue 120) as important determinants of VEEV virulence for mice.^{166,401} Attenuated viruses infect DCs less efficiently and replicate less well in lymphoid tissue and in the CNS than virulent viruses.^{487,759} Virulence for guinea pigs is determined by both envelope and nonenvelope genes.^{274,625} Determinants of equine virulence are different from determinants of murine virulence but also lie largely within the E2 glycoprotein.^{79,275,629} Changes most frequently associated with acquisition of equine virulence for ID strains are a Thr to Met change at position 360 of nsP3 and replacement of uncharged residues with Arg at positions 193 and 213 of the E2 glycoprotein.^{23,846} Acquisition of surface charge changes in E2 are also associated with emergence of epizootic IE strains.⁷⁹

Diagnosis, Treatment, and Prevention

Diagnosis can be made by virus isolation from blood or pharynx^{118,439,862} or by documenting the presence of anti-VEEV IgM or a rise in IgG antibody. HI, CF, neutralization, or EIA tests can be used for serologic diagnosis and nucleic acid amplification for detection of viral RNA. Antibody responses to enzootic versus epizootic strains can be differentiated with an epitope-blocking EIA.⁸⁴⁸

Treatment is generally supportive; however, passive transfer of antibody can protect mice before, or up to 24 hours after, challenge.^{263,340,341} The D-(-) enantiomer of carbodine, an inhibitor of cellular cytidine triphosphate synthetase, and antisense morpholino oligomers suppress VEEV replication *in vitro* and improve the outcome of infected mice.^{374,593}

The earliest vaccines developed for horses and laboratory workers were formalin-inactivated preparations.^{636,638} These vaccines had repeated problems with residual live virus producing disease and with poor immunogenicity and are no longer in use.^{404,629,860} A live attenuated vaccine (TC-83), developed by serial passage of the virulent TrD strain in guinea pig heart tissue culture cells,⁵⁸ is protective for horses and laboratory workers; however, 15% to 30% of recipients develop fever and pharyngeal viral shedding.⁶¹⁶ Therefore, a formalin-inactivated TC-83 vaccine (C-84) was produced.¹⁹⁶ Both the live and inactivated vaccines are immunogenic, although live TC-83 provides better protection against aerosol challenge in hamsters

than C-84 and is therefore preferred despite the reactogenicity.³⁶¹ To produce a more optimal vaccine, several experimental DNA, inactivated, and attenuated live virus vaccines are under development.^{131,191,192,500,594,643}

Several measures are effective in controlling outbreaks. These include immunizing equines, limiting equine movements from regions of infection, applying larvicides to mosquito breeding sites, and spraying insecticides to control adult mosquitoes.^{659,771,857} Protection of human populations relies primarily on personal protection from mosquito bites.

ALPHAVIRUSES ASSOCIATED PRIMARILY WITH POLYARTHRITIS AND RASH

Chikungunya

An outbreak of a crippling arthritic disease of sudden onset was first recorded in the Newala District of Tanzania in 1952.⁶⁶¹ Retrospective case reviews have suggested that CHIKV epidemics in Africa occurred as early as 1779 but were confused with dengue.¹¹¹ Because of the severe arthritic symptoms, the disease was given the name *chikungunya*, meaning “to walk bent over” in the Kimakonde language of Mozambique.^{328,661} The virus, isolated in 1953 from serum and from *Aedes* spp. and *Culex* spp. mosquitoes, was related to the group A arboviruses⁶⁶⁸ (see Fig. 23.5). Subsequent epidemics were recognized in the Transvaal of South Africa, Zambia, India, Southeast Asia, and the Philippines. From 2004 to 2007, a large epidemic affected islands in the Indian Ocean and India, with spread to Southeast Asia and Europe.^{628,654}

Epidemiology

CHIKV causes epidemics of rash and arthritis in India, Southeast Asia, Indonesia, the Philippines, most of sub-Saharan Africa, and Indian Ocean islands with recent extension into southern Europe.^{269,390,433,655,788} (Fig. 23.15). In Africa, the virus

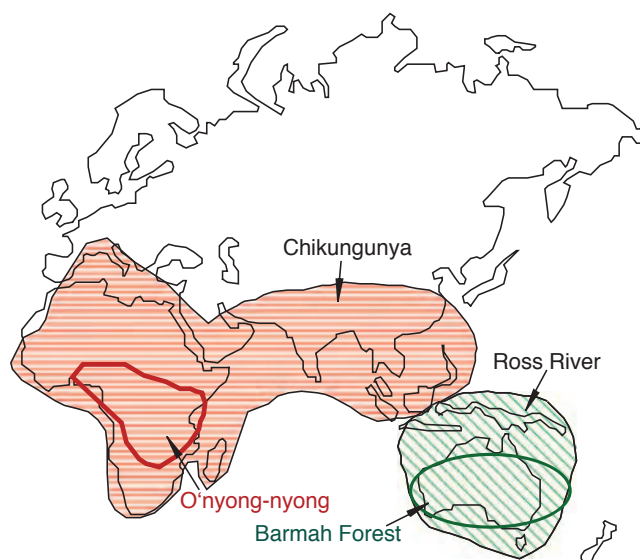

FIGURE 23.15. Geographic distributions of several alphaviruses that cause epidemic polyarthritis and rash: chikungunya, o'nyong-nyong, Barmah Forest, and Ross River viruses.

is maintained in cycles similar to that of yellow fever virus. There is a rural cycle involving *Aedes africanus*, *Aedes furcifer*, nonhuman primates, and other mammals and an urban cycle involving *Ae. aegypti* or *Ae. albopictus* and humans.^{137,177,812} In rural areas, the disease is endemic with small numbers of cases occurring most years.¹⁷⁷ In urban areas, outbreaks are sporadic and explosive, with infection of a large proportion of the susceptible population within a few weeks.^{250,601,654,661} In Asia, there is no evidence for a sylvatic cycle; rather, urban transmission is by *Ae. aegypti* and rural transmission is by *Ae. albopictus* in a human-mosquito-human cycle.^{326,568,627} Laboratory-acquired infections have also been reported.⁷⁹⁹

MORBIDITY AND MORTALITY

All ages and both sexes are susceptible to chikungunya, and disease is usually self-limiting and rarely life threatening. However, approximately 0.3% of cases are atypical or severe with nephritis, hepatitis, meningoencephalitis, thrombocytopenia, or encephalopathy. The case fatality rate has been estimated at 1 in 1,000, with most of the deaths either in neonates infected peripartum, adults with underlying conditions, or the elderly.^{119,195,654,660,707} The epidemic on Reunion Island affected almost 40% of the population (estimated 300,000 cases) and led to an excess of

254 deaths.^{250,318,653} Infants infected at birth are susceptible to CNS complications including cerebral edema and hemorrhage resulting in long-term disabilities.²⁴⁹ Musculoskeletal symptoms are recurrent or persistent in approximately 40% of adults and are more likely to affect females than males.^{752,887}

ORIGIN AND SPREAD OF EPIDEMICS

Outbreaks typically occur during the rainy season and are associated with increased population densities of mosquitoes.^{112,390,433,478} After an epidemic, the disease usually vanishes from an affected region for years, possibly because large portions of the population have become immune. The recent epidemics that began in Kenya in 2004 and spread to Comoros, Reunion Island, the Seychelles, Mauritius, and Mayotte in 2005 were associated with the emergence of a new strain that arose from the East African lineage^{382,705} (Fig. 23.16). Related outbreaks have been reported in India, Sri Lanka, Thailand, Malaysia, Singapore, France, and Italy, with imported cases recognized in many countries.^{318,598} Many of the recent outbreaks have been associated with a strain of virus that can be efficiently transmitted by *Ae. albopictus*.^{326,833} Because susceptible mosquitoes are widely distributed, travelers provide a source of CHIKV introduction into many other geographic regions.^{318,598,652,796}

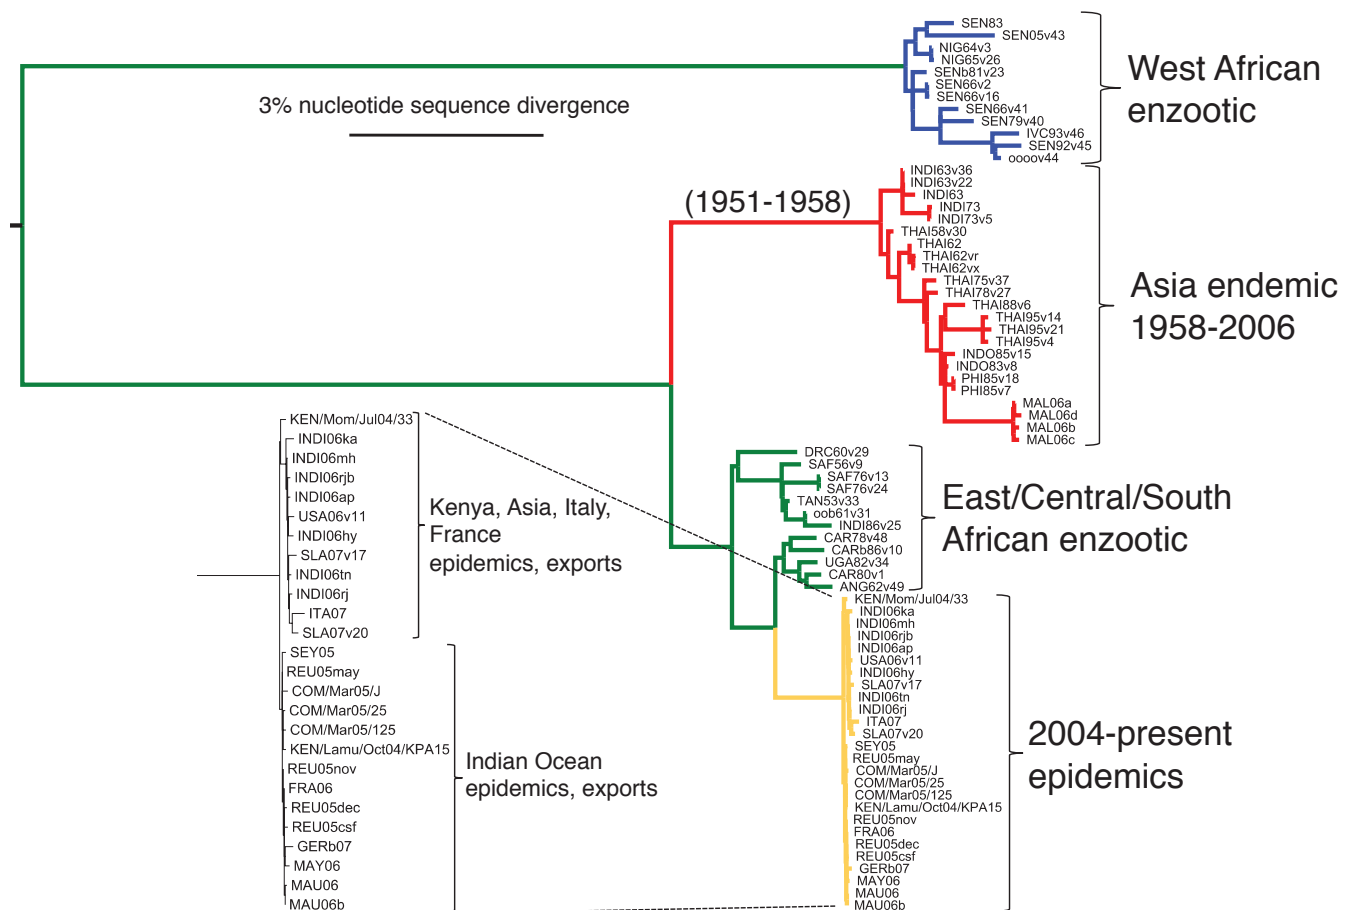

FIGURE 23.16. Chikungunya virus phylogenetic tree derived from genomic nucleotide sequences and Bayesian methods.

Strains are abbreviated with country followed by year of collection. All posterior probability values were 1.0 except for some within the 2004 to present epidemic clade shown in yellow. Estimated time frame for emergence of the 1958–2006 Asian endemic clade is indicated in parentheses. (Courtesy of Scott Weaver.)

There is some evidence that virus can be maintained within mosquito populations by low rates of transovarial or venereal transmission.^{506,639,795}

MOLECULAR EPIDEMIOLOGY

CHIKV is a member of the SFV complex, evolved from an ancestor in Africa, and was probably introduced into Asia 70 to 90 years ago.⁸³⁹ Two distinct lineages exist—one in western Africa and another in southern and eastern Africa and Asia.^{627,628,705} (see Fig. 23.16). In the latter lineage, the Asian strains group as a genotype distinct from the African strains, and analysis of isolates from recent outbreaks suggest that the Indian Ocean strains originated in Kenya and evolved separately from the viruses that spread to Sri Lanka, Singapore, and the Maldives.^{301,382,705,839} Analysis of genetic changes over time suggests positive selection driven by cellular immune responses to the virus and enhanced transmissibility by *Ae. albopictus*, an important vector for outbreaks, particularly in rural areas.^{301,568,705,800,813,833} Adaptation of endemic Asian strains to *Ae. albopictus* was restricted by interaction between threonine at E1–98 and the adaptive E1–226 alanine to valine substitution. This allowed African strains that had adapted to this vector to replace the endemic strains in many countries^{326,568,811,812–813} and possibly increase virulence.⁶²⁸

Clinical Features and Pathology

Chikungunya is of sudden onset with an incubation period estimated at 3 to 12 days.⁶⁶¹ No prodrome is recognized.¹¹² Fever rises rapidly to 103°F to 104°F and may be accompanied by a rigor. The onset of fever corresponds to the period of viremia and may be related to the ability of this virus to induce large amounts of type I IFN^{140,255,328,853} (see Fig. 23.7). Monocytes are infected and are a source of IFN during infection.³¹⁹ Virus titers in blood can reach greater than 10⁶ plaque-forming units (pfu)/mL, and viral load correlates with disease severity and IFN production.^{112,140,328,702} Joint pain appears suddenly and can be incapacitating. Essentially any joint can be involved, and pain may be accompanied by swelling and paresthesias.^{69,391,569} Headache, conjunctivitis, and gastrointestinal symptoms are common; in 80%, a maculopapular rash appears 4 to 8 days after the initial illness. The rash may be associated with a second rise in fever (see Fig. 23.7), lasts approximately 2 days, and is described as “irritating” or “itchy.”^{70,661} Atypical cases with severe disease and increased mortality can develop bullous dermatosis, encephalitis, myelopathy, pneumonia, and diabetes.^{142,195,778} Fibroblasts in skin and joints and satellite cells in muscle are targets for infection.^{155,590} Leukopenia is frequent.^{70,140,328,887} Plasma levels of TNF, IFN- γ , and MCP-1 are increased.⁶⁷²

Joint pains and myalgias may continue in a milder form for many months after the original illness.^{168,668,752} Chronic pain is more likely in females and those older than 60 years with a high viral load during the acute illness.^{328,887} Synovial tissue harbors persistently infected perivascular macrophages, fibroblast hyperplasia, activated NK cells, and CD4⁺ T cells but few CD8⁺ T cells.³²⁸ Cytokines are increased during the response to infection, and persistent arthralgia is associated with elevated plasma levels of IL-6 and granulocyte macrophage colony-stimulating factor.^{139,140,569} Joint x-rays are usually normal or show soft tissue swelling without evidence of bone or joint damage, although erosive arthritis has been reported.^{391,495} In

India, but not Africa, inguinal lymphadenopathy and red swollen ears are also observed as part of the clinical picture.¹¹²

Animal Models and Host Range

Mice and nonhuman primates can be infected with CHIKV. In wild-type mice, disease severity is age dependent.¹⁵⁵ Neonatal mice develop fatal disease.⁷⁸⁴ Two-week-old mice survive infection but develop weight loss, difficulty walking, myositis, foot swelling, tenosynovitis, and vasculitis.^{543,907} Local inoculation of adult mice causes foot swelling associated with macrophage infiltration and production of inflammatory cytokines, particularly TNF, IFN- γ , and MCP-1.^{244,672}

Fibroblasts are target cells for CHIKV infection and a major source of IFN- α/β .⁷⁰² Adult interferon α/β receptor (IFNAR)- and STAT1-deficient mice develop fatal disease with replication in the liver, muscle, joint, and skin fibroblasts and occasional dissemination to the choroid plexus, leptomeninges, and ependyma of the CNS.^{155,157,702} Infection of pregnant mice does not result in fetal infection.¹⁵⁷

Adult cynomolgus macaques infected intravenously or intradermally develop a dose-dependent viremia, fever, rash, liver enzyme elevation, arthritis, and meningoencephalitis.⁴²⁸ Peak production of IFN- α/β coincides with peak viremia. Pathology shows persistent mononuclear cell infiltration into lymphatic tissue, joints, muscle, and liver associated with prolonged presence of CHIKV RNA in macrophages at these sites.⁴²⁸ Pregnant rhesus macaques infected with enzootic West African and epidemic Indian strains of CHIKV develop viremia, rash, joint swelling, leucopenia, and cytokine increases after infection; however, fetuses did not become infected, providing further evidence that transplacental transmission is infrequent.¹³⁴

Diagnosis, Treatment, and Prevention

The primary differential diagnoses for chikungunya fever are dengue and o'nyong-nyong (ONN) fevers. Dengue overlaps the chikungunya geographic distribution extensively but is characterized more by myalgia than arthralgia.³⁹¹ ONN is clinically similar but has geographic overlap only in Africa¹¹² (see Fig. 23.15). Laboratory parameters are variable and not particularly helpful in the diagnosis.⁶²⁸ CHIKV can be isolated from plasma or detected by nucleic acid amplification during the initial fever.^{288,600,668,784} Detection of IgM antibody provides a means of early diagnosis and can persist for months, particularly in those with persistent symptoms.^{69,100,288}

Treatment is generally symptomatic with anti-inflammatory agents. Drugs that inhibit MCP-1 synthesis decrease muscle and joint inflammation in mice.⁶⁷² Passive transfer of immunoglobulin containing antibody to CHIKV can protect neonatal wild-type mice and IFNAR-/- mice from fatal infection.¹⁵⁶ IFN- α is protective in mice, although only if given prior to infection.²⁴⁴

A live attenuated vaccine (TSI-GSD-218) has been developed by passage of a CHIKV isolate from Thailand in MRC-5 cells.¹⁹⁷ This vaccine induces long-term production of neutralizing antibody, can be used to protect laboratory workers from infection,⁵⁰⁸ and is undergoing further development.⁶²⁸ A formalin-inactivated vaccine can elicit protective immune responses in mice.^{244,797} Additional approaches to vaccination include DNA, chimeric engineered viruses, and virus-like particles.^{18,398,494,617,796,847}

O'nyong-nyong

In 1959, an outbreak of a new disease, originally mistaken for dengue, was reported from northwestern Uganda.⁷²⁷ It is likely that a similar epidemic occurred in the same region in 1904–1906.⁷²⁷ The name *o'nyong-nyong* originated from one of the first tribes to be affected—the Acholi—and refers to the painful joints that are characteristic of the disease.²⁹⁵ During the 1959 outbreak, ONNV was isolated from the serum of a patient with acute arthritis⁸⁸⁴ and from anopheline mosquitoes.⁸⁸⁶ ONNV is a member of the SFV complex and antigenically is most closely related to CHIKV, from which it is estimated to have diverged thousands of years ago.^{627,884} The virus re-emerged in southern Uganda in 1996–1997, suggesting a 30- to 50-year epidemic cycle.⁴³¹ In 1967, Igbo Ora, now recognized to be a strain of ONNV,^{431,627} was isolated from humans in western Nigeria.⁵³⁷

Epidemiology

ONNV causes sporadic, widespread outbreaks of fever, rash, and arthritis with high attack rates. The first epidemic recognized originated in northwestern Uganda in 1959 and spread south and east to Kenya, Tanzania, Zaire, Malawi, Mozambique, and Zambia to affect more than two million people.⁸⁸⁵ More recent outbreaks of ONNV/Igbo Ora infection have been documented in West and Central Africa.^{60,422,453,622}

The enzootic vector and vertebrate reservoir host for ONNV are unknown. Interepidemic seroconversions and mosquito isolations indicate continuous sporadic transmission in East Africa, and it is possible that humans or nonhuman primates are the primary reservoir.⁴³¹ ONNV is transmitted principally by *Anopheles funestus* and *An. gambiae* and is the only alphavirus known to be transmitted by anopheline mosquitoes.^{486,886} Human-mosquito-human transmission occurs during epidemics, and spread from one region to another occurs through the movement of viremic humans.⁶⁸⁹ The most recent outbreak began near swamps and lakes in the rural Rakai District of south-central Uganda. Serosurveys showed infection rates of 45% to 96% in areas of epidemic transmission, with the ratio of apparent to inapparent infection ranging from 1:4 to 1:24.^{453,537,689} All ages and both sexes are equally susceptible.⁴⁰⁷ Among domestic animals in the same region, cattle have the highest seroprevalence (40%),⁵⁸² although the enzootic reservoir for this virus is not known.

Clinical Features and Pathology

The onset of fever associated with ONNV is sudden and often accompanied by a rigor. The characteristic syndrome includes joint pains, rash, lymphadenitis, and conjunctivitis. Fever is typically moderate (100°F–101°F) and lasts approximately 5 days. Joint pain most often occurs in the knees, although ankles, elbows, wrists, and fingers can also be affected. The pain usually lasts 6 to 7 days and is severe enough to be immobilizing in 80% to 90% of patients but can persist for up to 3 months. The generalized morbilliform maculopapular rash erupts 4 to 7 days after the onset of symptoms and is similar to that of chikungunya. It begins on the face and extends to the trunk and extremities, occasionally affecting the palms. Cervical lymphadenopathy distinguishes the disease from chikungunya, occurs in approximately half of patients, and most frequently involves posterior cervical lymph nodes. Leukopenia is common. Fatalities have not been described; however, morbidity is substantial.^{407,453,537,727}

Diagnosis

ONNV is often clinically confused with malaria, measles, dengue, and rubella^{622,727} but also resembles chikungunya. Virus can be isolated, or nucleic acid amplified, from blood early in the illness.^{60,622,885} Diagnostic serology includes a positive IgM EIA or neutralizing antibody to ONNV that is more than two-fold greater than that to CHIKV.⁶⁸⁹ IgM persists for about 60 days after infection.⁴⁰⁷

Ross River

Epidemics of polyarthritis in Australia probably date from at least 1886 but were first clearly described in towns on the Murrumbidgee River in New South Wales in 1928 and then in troops stationed in the Northern Territory and Queensland during World War II.^{306,353,489} Serologic studies suggested an alphavirus as the causative agent, and RRV (strain T48) was first isolated from *Ae. vigilax* mosquitoes trapped near the Ross River in Queensland in 1959.^{306,489} The first human isolate was made in 1971 from the blood of a child with fever.¹⁸⁴ In 1979, RRV spread from Australia to Fiji, Samoa, and the Cook Islands, causing an explosive outbreak of tens of thousands of cases of polyarthritis on these Pacific islands.³⁰⁶ Virus was first isolated from the serum of patients with polyarthritis during this epidemic.

Epidemiology

RRV is endemic throughout the coastal regions of much of northern and central Australia and epidemic in the rest of Australia, Papua New Guinea, and the Solomon Islands.^{666,790} In general, the Wallace and Weber hypothetical lines in the Indo-Australian archipelago that separate the fauna of the Oriental and Australian regions appear also to separate the geographic distributions of CHIKV and RRV⁴⁸⁹ (see Fig. 23.15). RRV is the most common mosquito-borne pathogen in Australia, with approximately 5,000 cases reported each year, an annual incidence of 14 to 50/100,000 population, and 10-year seroconversion rates of 24% in some areas.⁶⁷⁶ Cases are most common in the north and occur primarily in late summer and early autumn with some evidence of an increasing incidence.^{306,489,676} Two salt marsh-breeding mosquitoes—*Aedes camptorhynchus* and *Ae. vigilax*—are probably the major vectors in coastal regions of Australia.⁶⁷⁶ In inland areas, the freshwater-breeding mosquito *Culex annulirostris* is the major vector; in urban areas, *Aedes notoscriptus* appears to be involved in transmission.⁶⁷⁶ Various mammals, primarily macropods such as kangaroos and wallabies, and potentially pteropid bats, appear to serve as vertebrate hosts for the enzootic cycle.^{116,306,676} In urban areas, horses and brushtail possums are likely involved in transmission.³⁸⁶

MORBIDITY AND MORTALITY

Infection rates can be as high as 1:30 during outbreaks.⁴⁸⁹ Estimates of apparent to inapparent infections range from 1:3 to 1:1.^{306,772} Seroprevalence and disease incidence are similar in males and females. Clinically apparent infections are rare in children, and the highest incidence of disease is in the 25- to 40-year age group.^{306,353}

ORIGIN AND SPREAD OF EPIDEMICS

In Australia, outbreaks are seasonal and have been associated with prolonged inundation of salt marshes owing to increased tidal heights or heavy rains during the summer.^{339,353,489,801,883}

and with a loss of herd immunity in reservoir populations.¹¹⁶ In arid regions, outbreaks often occur within 2 or 3 weeks of heavy rains, suggesting that RRV survives in desiccation-resistant mosquito eggs with vertical transmission.⁴⁶³ This is further suggested by isolation of RRV from field-caught immature and male *Ae. vigilax* and *Aedes tremulus* mosquitoes.⁴⁶³ Both urban and rural cycles of transmission occur. Epidemic polyarthritis, initiated by a viremic traveler from Australia to Fiji, spread to several South Pacific Islands between 1979 and 1980 in explosive outbreaks similar to urban chikungunya, with a man-mosquito-man transmission cycle and *Aedes polynesiensis* as the vector.^{666,790} Human viremias of more than 10⁶ mosquito infectious dose 50 (ID₅₀)/mL have been documented.⁷⁹⁰ Cases in travelers suggest that RRV has been reintroduced to Fiji.⁴⁰⁸

MOLECULAR EPIDEMIOLOGY

Strains of RRV originally isolated from the northeastern (Queensland), southeastern (New South Wales), and western regions of Australia are antigenically and genetically distinguishable.^{371,687,888} However, the northeastern lineage has not been recovered since 1977 and, along with the western lineage, has been replaced by the southeastern lineage.^{1,371} This replacement accompanied the appearance of duplication in the C-terminal domain of nsP3 first identified in a virus recovered in 1979 from a patient in Fiji.^{1,5} The data suggest genetic divergence and independent evolution of RRV within geographically isolated enzootic foci consistent with mammals as a vertebrate reservoir.⁶⁸⁷ However, overall diversity is low, perhaps owing to purifying selection.³⁷¹ Sequencing of intrahost populations of RRV reveal substantial diversity and evidence of mixed infections.⁴⁶⁷

Clinical Features and Pathology

RRV infection most often induces fever, arthralgia, and rash (see Fig. 23.6), although not all patients develop all three symptoms.^{308,788} Usually the illness has a sudden onset. Fever is the initial symptom, which is low grade, and is typically followed by the onset of pain, swelling, and tenderness in multiple joints. Joint involvement is usually symmetrical, and both small and large joints can be affected. Characteristically, the rash appears on the third or fourth day of illness; is maculopapular, nonpruritic, and present on the face, trunk, and extremities with occasional involvement of the palms and soles; and generally lasts 3 to 4 days.²²⁸ Frequent accompanying signs and symptoms include lymphadenopathy, lethargy, headache, myalgias, and photophobia. The average period of incapacity is 6 weeks, and symptoms gradually resolve in most affected individuals over 3 to 6 months.^{304,308}

Examination of synovial fluid shows increased protein; the presence of CD4⁺ T lymphocytes, monocytes, and activated macrophages; and increased levels of TNF, IFN- γ , and MCP-1.^{145,229,460} Cell counts are moderately increased, ranging from 1,500 to 15,000 cells/mm³,²²⁹ and RRV RNA is present.⁷⁴⁷ RRV replicates in, and can cause persistent infection of, synovial macrophages *in vitro*.⁸⁵⁴ It is postulated that infection of these cells leads to cytokine production and inflammatory arthritis *in vivo*.⁷⁷²

The skin lesions show mononuclear perivascular inflammation without evidence of immune complex deposition. Most of the infiltrating cells are CD8⁺ T lymphocytes. RRV antigen is present in the basal epidermal and eccrine duct epithelial cells.²³⁰

Animal Models and Host Range

Despite its extensive host range, RRV induces clinically evident disease only in humans, mice, and horses.^{43,783} The prototype T48 strain has been extensively passaged in mice, and virulence is age dependent.^{526,554} In newborn mice, T48 infects cardiac muscle, causing myocardial necrosis and death 3 to 4 days after infection.^{554,715} One-week-old mice survive, and infection of the CNS leads to demyelination and destruction of the internal granule cell layer of the cerebellum.⁷¹⁵ In 2- to 3-week-old mice, RRV causes myositis, arthritis, and weakness, with virus replication in muscle, perichondrium, periosteum, and skin.^{545,554} Macrophages are prominent components of the disease-inducing inflammatory process.^{460,673} Soluble mediators that contribute to disease severity include complement, TNF, IFN- α/β , IFN- γ , MCP-1, and macrophage inhibitory factor (MIF).^{321,459,460,542,544} Adult mice develop an asymptomatic viremia that persists for 5 to 9 days.⁷²⁰ In pregnant mice, virus can replicate in the placenta and spread to the fetus.⁵²⁴

The less virulent NB5092 strain induces severe myositis and muscle cell death in newborn mice after subcutaneous inoculation.⁵⁵⁴ Mice become stiff and unable to move and then gradually regenerate muscle and recover function after virus is cleared.⁵⁵⁴ CNS disease is minimal, with patchy infection of ependymal cells and ependymitis leading to hydrocephalus. Neurons are only occasionally infected.⁵²⁶ Brown fat is another important site of virus replication.⁵⁵⁴ By 1 week of age, mice no longer develop signs of disease.⁵⁵⁴

Virulence

To identify determinants of virulence for mice, virulent T48 has been compared to the less virulent NB5092 and DC5692 strains with different passage histories.^{206,240} Virulence has been associated primarily with amino acid differences in nsP1 and E2.^{379,395,517,783,841,842} Changes in nsP1 affect disease without affecting virus replication, whereas changes in E2 usually affect replication. Induction and susceptibility to IFN also influence disease development.⁴⁵⁹ Of unproven but possible significance is the fact that the epidemic strain of RRV in the Pacific differed from the parent Australian strain by a change from Thr to Ala at E2-219 and duplication in nsP3.^{1,93}

Diagnosis, Treatment, and Prevention

Diagnosis is aided by geographic location and travel history. The differential diagnosis includes rubella, other alphavirus-induced arthritides, and Henoch-Schönlein syndrome.²²⁸ Virus can be recovered from blood early in disease^{666,790}; however, most diagnoses are made using serology. The most sensitive and commonly used serologic test is an IgM capture EIA that can remain positive for 1 to 2 years after the onset of disease.¹¹⁵

In mice, treatment with sulfasalazine to block NF κ B or with bindarit to inhibit MCP-1 synthesis decreases inflammation and tissue damage.^{460,671} In contrast, treatment with etanercept to block TNF enhances virus replication, inflammation, and tissue damage.⁸⁹⁸

Vector control and personal protection against mosquito bites remain the primary means of prevention.^{305,798} An aluminum hydroxide adjuvanted inactivated whole virus vaccine that protects mice from infection and disease induces neutralizing antibody in humans at levels predicted to be protective and is in clinical development.^{2,17,330}

FIGURE 23.17. Geographic distribution of Sindbis virus. Northern Europe and South Africa, regions with significant outbreaks of arthritis, and rash disease in humans are designated in blue.

Sindbis

The prototype strain of SINV—AR339—was initially isolated from *Culex univittatus* mosquitoes collected near Sindbis, Egypt, in 1952.⁷⁸² Humans living in the Nile Delta at that time had a seroprevalence of 27%, although no disease was associated with infection.⁷⁸² Over the next 25 years, SINV was isolated in Europe, the Middle East, Africa, India, Asia, Australia, and the Philippines from various mosquito and vertebrate species. SINV was first isolated from the blood of febrile humans in Uganda in 1961 and recognized in South Africa as a cause of rash and arthritis in 1963.⁴⁹³

Epidemiology

SINV is the most widely distributed of the alphaviruses causing arthritis in man (Fig. 23.17). The primary sites of recognized SINV-mediated human disease are in northern Europe (Ockelbo in Sweden, Pogosta fever in Finland, and Karelian fever in Russia)²⁰³ and South Africa.³⁸⁰ In the many other regions where the virus exists, human infection occurs but results only in subclinical disease, fever, or mild arthralgias. The basic maintenance cycle of SINV is between *Culex* spp. or *Culiseta* spp. mosquitoes and wild birds.⁴⁸⁹ In Sweden, the enzootic cycle involves *Culex torrentium*, *Culiseta morsitans*, and passerine birds.^{227,480,482} In Finland, grouse are an important vertebrate host.⁴²⁵ Vertical transmission in mosquitoes can occur.¹⁷⁶

MORBIDITY AND MORTALITY

The age-adjusted prevalence for SINV is 2% to 8% in endemic regions of northern Europe and 0.1% to 0.2% in neighboring nonendemic areas. Risk is highest between the 60th and 64th parallels and is associated with spending time in the woods or marshland and exposure to mosquito bites.^{88,203,425,479,691} The ratio of symptomatic to asymptomatic cases is 1:17, with 45- to 65-year-old women most likely to develop disease.⁸⁸

ORIGIN AND SPREAD OF EPIDEMICS

Spread of SINV from its enzootic cycle between birds and ornithophilic mosquitoes to humans involves bridge vectors with less specialized feeding habits⁸¹⁷ (see Fig. 23.10). In northern Europe, the primary bridge vector is *Aedes cinereus*, and availability of this species may determine the frequency of human infection. Cases begin to appear in late July and continue into the fall. Large outbreaks occur approximately every 7 years, perhaps in association with fluctuating grouse populations.^{479,690}

MOLECULAR EPIDEMIOLOGY

Antigenic and genetic analyses of strains from different locations indicate the presence of five geographically distributed distinct genotypes: Africa and Europe (I), Australia (II), East Asia (III), Azerbaijan and China (IV), and New Zealand (V, Whataroa).^{481,482,686,688} Strains isolated in northern Europe and South Africa, where most SINV-induced disease occurs, are more closely related to each other than to strains isolated in south and central Europe and the Middle East, where disease is rare.^{372,724} The phylogeographic distribution is consistent with migratory birds as the major vertebrate host.^{481,688}

Clinical Features

The primary clinical manifestations are itching rash, arthritis, fever, and muscle pain.^{203,424,820} The rash is distributed diffusely over the trunk and limbs and can affect the palms and soles. Skin lesions have a macular base with central vesicle formation and are occasionally hemorrhagic.^{203,493} Joint pain preferentially affects large joints and may be severe enough to be immobilizing. Macrophages infected with SINV become activated; release MIF, TNF, IL-1 β , and IL-6; and express matrix metalloproteinases.³¹ Most patients recover within 14 days; however, joint pain and stiffness may persist for months to years.^{203,424,820} In Australia, SINV-induced arthritis and rash is milder and less frequent than RRV-induced disease or SINV-induced disease in northern Europe and Africa.⁴⁸⁹

Animal Models and Host Range

SINV can infect various vertebrates and has been extensively studied in mice as a model for acute encephalitis. In mice, there is an age-dependent susceptibility to fatal encephalitis.³⁶⁹ In young mice, virus replicates to high titer and spreads rapidly, causing death in 3 to 5 days. In older mice, virus replication is more restricted, and they often recover. After peripheral inoculation, virus replicates in muscle, produces a viremia, and then spreads to the brain and spinal cord, where the primary target cells are neurons.³⁴⁹ Ability of SINV to spread to the CNS and cause fatal disease depends on the strain of virus and the genetic background of the mouse.^{350,483,484,721,792,814} C57BL/6 mice are most susceptible to fatal encephalomyelitis after infection with neurovirulent strains, and this is determined in part by a gene on chromosome 2.^{792,793,814} Neuronal death requires contributions of the host, such as glutamate excitotoxicity and immunopathology.^{163,273,563,669} Deficiencies of IFN signaling or acid sphingomyelinase increase susceptibility to fatal encephalitis.^{95,567}

In nonfatal encephalitis, neutralizing antibody and an SINV-specific perivascular mononuclear inflammatory response consisting of T cells and monocytes appears within 3 to 4 days after infection.⁵²⁹ Spread of infection is limited initially by IFN- α/β ,⁹⁵ and infectious virus is cleared within 7 to 8 days after

infection, primarily through the effects of antiviral antibody and IFN- γ .^{64,89–91,286,448} Viral RNA persists in the CNS after clearance of infectious virus, and reactivation of infection appears to be prevented by continued presence of T lymphocytes and antibody-secreting B cells within the CNS.^{285,447,521,821}

Virulence

Strains of SINV differing in virulence have been derived from independent isolates from Egypt (AR339), South Africa (SR86), and Israel (SV-Peleg). Variants of AR339 and SV-Peleg differing in virulence have been derived by passage in mice and in tissue culture.^{284,483} Virulence is determined primarily by the 5' NTR and the E2 glycoprotein but can be influenced by changes in E1 and the nsPs.^{165,485,513,773} Changes in nucleotide 5 or 8 from A to G increase neurovirulence by unknown mechanisms.^{188,513} Several amino acid changes in the E2 glycoprotein affect virulence by altering efficiency of virus entry into the CNS or by enhancing neuronal infection.^{54,165,438,815} Neuroinvasion is affected by changes at residues 55 and 190 of E2.¹⁸⁸ A Gln to His change at E2-55 increases efficiency of infection of neurons and is a major determinant of increased virulence in older mice.^{438,815}

Diagnosis, Treatment, and Prevention

The major differential in SINV is with other causes of acute rash and arthritis, such as parvovirus B19 and rubella. The virus can be recovered from skin lesions and from blood.^{423,424,493}; however, the diagnosis is most often made by serology. SINV-specific IgM increases during the acute phase of the disease and then tends to decrease slowly for 3 to 4 years, independent of persistent symptoms.⁵⁷¹

Mice can be protected from fatal encephalitis by treatment with drugs that inhibit inflammation and glutamate excitotoxicity.^{273,348,631} Mice can also be passively protected with antibody but develop progressive destruction of infected regions of the brain.³⁹⁹

Barmah Forest

Barmah Forest virus (BFV) was first isolated in 1974 from *Cx. annulirostris* mosquitoes collected in the Barmah Forest in the Murray River Valley region of southeastern Australia and soon thereafter in southwest Queensland.²⁵ It is the only recognized member of the BFV complex and has a unique E2 protein without N-linked glycosylation.^{418,437} Human disease was first reported in 1986 with an epidemic of polyarthritis in New South Wales,⁷¹ and BFV was first isolated from the blood of a patient in 1988.⁶⁰⁹ The geographic range of BFV is expanding.⁸⁰² In 1989, BFV—previously restricted to eastern portions of Australia—was isolated in western Australia with subsequent outbreaks of human disease.⁴⁶⁴

The vertebrate reservoir host is unknown; however, serosurveys suggest that horses and marsupials, particularly brushtail possums, may play a role.^{386,464} On the other hand, sequence analysis shows a high degree of homology over the geographic distribution consistent with an avian vertebrate host.⁶²⁰ The main mosquito vectors are not well established but appear to include *Cx. annulirostris*, *Ae. vigilax*, *Ae. notoscriptus*, and *Ae. camptorhynchus*.^{352,464} Transmission in coastal areas is influenced by temperature, tides, and socioeconomic factors.⁵⁶²

Disease is most common in the 30- to 50-year age group, with men and women equally affected.⁵⁵ The most common clinical features are fever, lethargy, polyarthritis, and myalgia accompanied by a vesicular rash.^{25,55,609} Diagnosis may not be made because the illness is frequently mild and overlaps the clinical spectrum and geographic distribution of RRV and SINV infections (see Figs. 23.15 and 23.17). Rash is more prominent in BFV, whereas arthritis is more prominent in RRV²¹⁶ and the serology is distinct.⁶⁰⁹ In over half of infected individuals, recovery takes several weeks, with lethargy the most prominent persisting symptom.⁵⁵

Mayaro and Una

Mayaro virus was first isolated in 1954 from febrile forest workers in Trinidad and then from several individuals with fever and frontal headache in the Guama River area of Brazil.^{22,122} The virus is widely distributed in South America.^{220,505,791} Human cases are sporadic and occur primarily in persons with recent contact with humid tropical forests.⁸⁰⁵ There are two distinct genotypes. Genotype D contains isolates from Trinidad and north central South America, and genotype L contains isolates from Brazil.⁶²⁴ The principal mosquito vectors are in the forest-dwelling genus *Haemagogus*, and the vertebrate hosts are mammals, mainly nonhuman primates. Airborne transmission to laboratory personnel has also occurred.³⁷⁸ Symptoms include fever, headache, arthralgia, myalgia, vomiting, diarrhea, and rash that last from 3 to 5 days.⁵⁰⁵ The diagnosis can be made by isolation of virus from blood or by serology using an IgM capture EIA.¹⁰⁰ Una virus is closely related to Mayaro virus and was first isolated from *Psorophora ferox* mosquitoes in the Amazonian region of Brazil in 1959.¹²¹ It is widely distributed in Central and South America.^{121,178,179} Vertebrate hosts include nonhuman primates.¹⁷⁸ This virus is pathogenic for mice but is not recognized to cause human disease.

OTHER ALPHAVIRUSES

Semliki Forest

SFV was first isolated in 1942 from *Aedes abnormalis* collected in the Semliki Forest of western Uganda.⁷⁴³ It is widely distributed in Africa with mosquito (e.g., *Ae. africanus*, *Aedes argenteopunctatus*) isolates documented from Mozambique, Nigeria, and the Central African Republic.^{491,504,511} Although SFV is one of the most extensively studied of the alphaviruses and serosurveys indicate that human infection is relatively common,^{333,504,743} SFV has been linked to human disease on only two occasions. In the first case, reported in 1979, a 26-year-old laboratory worker in Germany with a 1-year history of “purulent bronchitis” working with the Osterrieth strain of SFV developed fever and headache followed by seizures, coma, and death from encephalitis. SFV was isolated from CSF and from brain. No antiviral antibody was detectable at the time the CNS symptoms began, although it was detected at the time of death 1 week later.⁸⁸² The history of chronic pulmonary infections and failure to produce antiviral antibody rapidly suggest that this individual had an immunodeficiency disorder involving antibody production. In 1987, SFV was isolated from serum samples of individuals in the Central African Republic with fever, persistent headache, myalgias, and arthralgias.⁵⁰⁴

Animal Models

SFV can cause encephalitis in horses, mice, rats, hamsters, rabbits, and guinea pigs.^{36,75,743,908} Severity and type of disease depend on the age of the animal at the time of infection, the route of inoculation, and the virulence of the strain of SFV used for infection.^{75,287} Mice have been most extensively studied, and the strain of inbred mouse infected can also influence outcome.⁷⁶⁹

In newborn and suckling mice inoculated peripherally, virulent and avirulent strains of SFV replicate rapidly and extensively in muscle, elicit a high-titered viremia, spread to the CNS, and cause death within 2 to 4 days.^{208,287,553} Evidence suggests that SFV enters the brain across cerebrovascular endothelial cells.^{208,396,748} Once within the CNS, the virus replicates primarily in neurons and spreads rapidly along neural pathways, producing neuronal cell death.⁵⁸⁴

In weanling (3- to 5-week-old) mice, SFV replicates rapidly but reaches lower peak titers in muscle, blood, and brain than in younger animals.²⁸⁷ Virus enters perivascular regions of the brain and initiates foci of infection within the CNS. After intranasal inoculation, virus infects olfactory neurons first and then spreads within the CNS.⁵⁸⁴ The primary target cells in the brain are neurons, although oligodendrocytes are also infected.^{36,208,396} Neurons control virus replication more effectively than oligodendrocytes.²²⁶ A mononuclear inflammatory response consisting of T lymphocytes, B lymphocytes, and monocytes is apparent 3 to 4 days after infection, peaks at 2 to 3 weeks, and is mostly resolved by 6 weeks.⁵⁴¹

Mice infected with virulent strains can be passively protected from fatal encephalitis with immune serum but then develop a delayed disease associated with persistent infection, inflammation, and neuronal degeneration.⁷¹² Mice that survive infection develop demyelination, which is accompanied by mild paralysis, 2 to 4 weeks after infection.^{138,770} Clearance of infectious virus is complete 7 to 10 days after infection, and this clearance is mediated by antibody.²⁰⁸ Viral RNA and protein persist for months.^{186,396} Focal areas of demyelination are found 14 to 21 days after SFV infection and are characterized initially by swelling and vacuolation of oligodendrocytes and loss of myelin sheaths followed by remyelination.⁹⁴ Demyelination is macrophage mediated and appears to be the result of oligodendrocyte infection, the immune response to infection, and induction of an autoimmune response to myelin.^{209,532,768} SJL mice have prolonged inflammatory responses and demyelination after infection compared with other strains of mice.^{186,744}

SFV infection of the CNS can also increase the susceptibility of mice to induction of experimental autoimmune encephalomyelitis,⁵³³ apparently by damaging the blood-brain barrier, increasing adhesion molecule expression on endothelial cells, and facilitating entry of autoimmune T lymphocytes into the CNS.^{748,749}

Virulence

Isolates from mosquitoes collected in 1942 in Bwamba, Uganda,⁷⁴³ in 1948 in Kumba, Nigeria,⁴⁹¹ and in 1959 in Namacurra, Mozambique⁵¹¹ have given rise to various laboratory strains of SFV with differing levels of virulence. The most commonly studied are virulent strains V12, V13, and L10 (Uganda strain independently passaged in mice in Bethesda [V] and London [L]) and avirulent strain A7 (Mozambique strain AR2066 passaged in mice) and its less virulent derivative A7-74.⁷⁵ In

addition, avirulent strains of L10 have been derived by chemical mutagenesis (e.g., m9).⁴⁸ Virulent and avirulent strains differ in their ability to invade and replicate in the CNS of weanling mice and rats after peripheral inoculation, although all strains cause fatal disease in newborn or suckling mice.^{36,208,287,553} In 3- to 4-week-old mice, avirulent SFV is restricted in replication and spread in the CNS compared to virulent strains of virus and compared to avirulent strains in younger mice.⁵⁸⁵ This difference in replication is associated with decreased budding of infectious virus and is independent of the host immune response.²⁰⁸ Mature neurons and pancreatic and myocardial cells can be made more susceptible to avirulent virus by treatment with aurothiomalate compounds that induce intracellular membrane proliferation.^{208,700} In general, reduced virulence correlates with reduced replication in neurons.⁴⁴

In vitro studies of the differences between virulent and avirulent strains of SFV have shown differential replication in neuronal cells³⁴ and differences in susceptibility to IFN.¹⁷⁴ Efforts to identify specific nucleotide and amino acid changes important for virulence have utilized comparative sequence analysis and an infectious SFV cDNA clone pSP6-SFV4 derived from the prototype virulent L10 strain. Construction of SFV4/A7 chimeric viruses has shown that determinants of virulence reside in both the structural and nonstructural regions of the genome.⁷⁷⁹ E2, nsP2, and nsP3 are important determinants of virulence.^{208,256,259,658,693}

Other Semliki Forest-Related Viruses

The SFV complex includes eight viruses and has representatives in both the Old World (Bebaru virus, chikungunya, Getah, ONN, Ross River, and Simliki Forest) and the New World (Mayaro and Una) (see Table 23.1 and Fig. 23.5). Recently identified southern elephant seal virus is phylogenetically, but not antigenically, related to SFV. Human disease, when present, is generally characterized by fever that may be accompanied by arthritis and rash. CHIKV, ONNV, RRV, and SFV have been discussed previously.

Getah

Getah virus was first isolated from *Culex* spp. mosquitoes collected in Malaysia in 1955 and causes myositis when inoculated into mice.³²⁵ It is maintained in a cycle similar to Japanese encephalitis virus with transmission by *Culex tritaeniorhynchus* and amplification in domestic pigs.⁷³⁵ Getah virus is widespread and ranges from Eurasia to Southeast and Far East Asia, the Pacific Islands, and Australasia. Disease in humans is limited to fever,⁴⁵⁶ although it causes abortion in pigs and is an important pathogen of horses.⁷¹⁷ The equine disease is characterized by fever, an urticarial rash, and hind leg edema but is not life threatening.⁷¹⁷

Southern Elephant Seal

Southern elephant seal virus was isolated from lice residing on southern elephant seals on Macquarie Island, Australia. It is phylogenetically related to SFV but does not cross-react serologically. No disease has been recognized in infected seals.⁴²⁷

Salmonid Alphavirus

Salmonid alphavirus (SAV) causes sleeping disease in rainbow trout and pancreas disease in farmed Atlantic salmon.^{329,836,875,876} SAV has unusually large E1 and E2 structural glycoproteins

and relatively low (30%–34%) homology to other alphaviruses.^{836,876} Six subtypes have been identified.⁷⁴⁵ Subtypes 1, 4, and 5 are closely related and have been isolated from farms in Britain with pancreas disease. Subtype 2 causes sleeping disease in Europe, and subtype 3 causes disease on salmon farms in Norway. Subtype 6 is represented by a single isolate from Ireland. SAV causes significant disease on fish farms, which is characterized by abnormal swimming behavior and lack of appetite. Histopathology shows degeneration of the pancreas and of cardiac and skeletal muscles.⁵¹⁵ SAV is shed in feces and mucus and can be horizontally transmitted.²⁶⁸ Sea lice can be infected; however, their role in transmission is unclear.⁶⁰⁶ Subtype 5 SAV RNA sequences have been detected in wild marine fish, suggesting that marine reservoirs exist.⁷⁴⁶

DIAGNOSIS

The differential diagnosis of alphavirus-induced diseases often includes more than one alphavirus in addition to other mosquito-borne viral diseases such as dengue and West Nile fevers, other rash diseases such as rubella and parvovirus B19, and other causes of encephalitis. IgM capture EIAs can be used for diagnosis early in disease.^{99,100,103} The IgM response is relatively specific for each antigenic complex and is useful even at later times, because IgM persists for at least 2 to 3 weeks after onset of disease.¹⁰⁰ Virus isolation and identification remain useful; however, nucleic acid amplification tests have simplified virus identification in clinical samples.⁶³⁰ RT-PCR primers have been designed that can amplify the conserved region of all alphaviruses,^{201,290,608} as well as alphavirus-specific regions,⁴³⁰ and should be useful for rapid diagnosis.

PREVENTION AND CONTROL

Treatment

At this time, there is no available specific antiviral treatment for any alphavirus-induced disease, although compound screening has identified potential antiviral therapies for evaluation in animals.^{170,374,377,593,604,619,645} Therapeutic MAbs and immune system activators are being evaluated in animal models.^{341,470} Several neuroprotective drugs protect mice from fatal encephalitis.^{163,273,348,563,631} Supportive treatment for those with encephalitis can be lifesaving because individuals may make remarkable recoveries from coma. Symptomatic treatment for arthritis with anti-inflammatory drugs and immune modulators can be beneficial.

Vaccines

Formalin-inactivated vaccines against EEE, WEE, and VEE are available for horses and against EEE for birds. Experimental inactivated vaccines against EEE, WEE, and VEE are also available for laboratory workers exposed to these agents, with yearly booster doses required for EEE and WEE.¹⁹⁶ PE-6—the investigational inactivated EEE vaccine for humans—induces good immunoreactivity against the NA-EEEV but not SA-EEEV.⁷⁶⁷ An inactivated VEE vaccine that uses the V3526 strain is under evaluation,⁵⁰⁰ and an inactivated RRV vaccine is in human trials.¹⁷

Live attenuated vaccines have been developed for VEEV (TC-83) and CHIKV.⁴⁵⁰ Substantial side effects are common after immunization with TC-83,^{196,616} and new attenuated strains are under investigation.^{594,643} Alternative approaches in preclinical development include MAbs, DNA vaccines, chimeric alphaviruses, alphavirus replicons, and adenovirus-vectored vaccines.^{191,192,263,340,594,774} In both horses and humans, prior vaccination against one alphavirus can interfere with development of neutralizing antibody to subsequent alphavirus vaccines.^{106,181,508,615}

Other

Prevention of infection with most alphaviruses relies primarily on efforts to control mosquito populations by spraying and reducing breeding places. Various means can be used for assessing the need for mosquito abatement. These include monitoring mosquito population densities, seroconversion of sentinel animals, and presence of virus in populations of mosquitoes capable of transmitting virus to humans or domestic animals. Individual use of protective measures, such as mosquito repellents and protective clothing, are important.

PERSPECTIVE

The ability to construct full-length cDNA alphavirus clones that can be transcribed into infectious RNA has advanced understanding of the functions of various genes and their importance for replication and virulence in the multiple hosts necessary for maintenance of these viruses in their natural cycles. An understanding of the three-dimensional structures of proteins in the virion has greatly aided interpretation of much of the sequence and virulence data previously acquired. Further sequence information on virulent and avirulent strains, functional and structural analysis of the nsPs, and assessment of host–cell interactions is likely to provide the next level of understanding of virus–host relationships.

In addition, there is a need for improved approaches to prevention and treatment. There is a particular need for understanding the components of the immune response necessary for noncytolytic virus clearance, protection from reinfection, and immune modulation of disease. New and improved vaccines are needed for protection during outbreaks and for laboratory workers. In addition, there is a need for effective anti-alphaviral drugs, and an understanding of the structure of viral proteins may offer new approaches to therapeutics. Both of these areas have implications for biological defense purposes, because many alphaviruses can be transmitted by aerosol and VEEV, EEEV, and WEEV are on the U.S. Centers for Disease Control and Prevention category B list of critical biological agents.¹²⁴

Perspective

Rubella virus (RV) is the etiologic agent of *rubella*, a mild exanthematous disease associated with low-grade fever, lymphadenopathy, and a short-lived morbilliform rash. Rubella was first described as a distinct disease in the early 1800s.¹⁴³ Prior to acquiring its more common name, the disease was named *Rōtheln* by the German physician de Bergen,⁶⁵ leading to the common name of German measles, a milder form of the much more serious exanthem caused by the paramyxovirus, measles virus. Subsequently, in 1866 the disease name was anglicized to *rubella* by the British physician Veale.²⁴³

Predominantly a childhood disease, RV is endemic in many parts of the world. The introduction of comprehensive vaccination programs in most industrialized regions including the Americas, Western Europe, Japan, and Australia has drastically reduced the incidence of disease in these areas. Indeed, the indigenous circulation of rubella was officially declared eliminated in the United States in 2005. However, developed nations are still very much at risk for rubella outbreaks due to immigration from areas where RV vaccination is lacking. For example, in Africa and Southeast Asia, scheduled infant immunization against rubella is 0.1% and 4%, respectively.²⁵⁸ Because a very large proportion of the world's population is still

susceptible to RV (Fig. 24.1), we can expect that epidemics of rubella will still occur on a regular basis.

Until the keen observations of the ophthalmologist Norman Gregg, rubella was considered a relatively benign infection, associated with considerably less morbidity than measles. In 1941, Gregg encountered a large number of children with cataracts, many of whom had additional serious congenital defects. He noted that an apparent epidemic of congenital cataracts was directly preceded by a large rubella outbreak. Gregg proposed that the cataracts and the often associated congenital cardiac abnormalities were the consequence of maternal infection during pregnancy.⁸³ Further studies by other investigators confirmed that the virus could have devastating effects on a developing fetus when acquired by the mother in early pregnancy.²⁵⁴ The realization that viruses can act as teratogenic agents spurred the efforts to develop an attenuated vaccine.

A key step in vaccine development was isolation and growth of RV in cultured cells.^{182,255} In 1969, the first rubella vaccine was licensed in the United States, 5 years after the last major epidemic in that country and shortly before the next significant outbreak was predicted to occur. Fortunately, no other major rubella epidemics occurred, largely in part because of the adoption of universal vaccination in infancy, which has been remarkably successful in controlling natural rubella and its devastating teratogenic effects.²¹³

INFECTIOUS AGENT

RV is an enveloped positive-strand RNA virus in the family *Togaviridae*. There are two genera that compose the *Togaviridae*: *Alphavirus*, which includes Sindbis and Semliki Forest viruses, and *Rubivirus*, whose sole member is RV. Togaviruses share a common genome organization and replication strategy (Fig. 24.2). Whereas alphaviruses employ animal reservoirs and arthropod vectors for transmission, humans appear to be the only natural host and reservoir for RV. Although only one serotype exists, there are at least 10 genotypes of RV (Fig. 24.3), which can be grouped into two clades.²⁶⁴ Circulation of clade 2 viruses, which contain three genotypes, is limited to Eurasia, while clade 1 viruses are more widely distributed. The genome of RV is a 5' capped positive-sense RNA molecule of approximately 10 kilobases (kb) with a poly (A) tail. There is no serologic cross-reactivity between the alphaviruses and RV, and only limited genome sequence similarity, predominantly within the nonstructural genes in regions that encode functional domains such as the polymerase and protease activities.

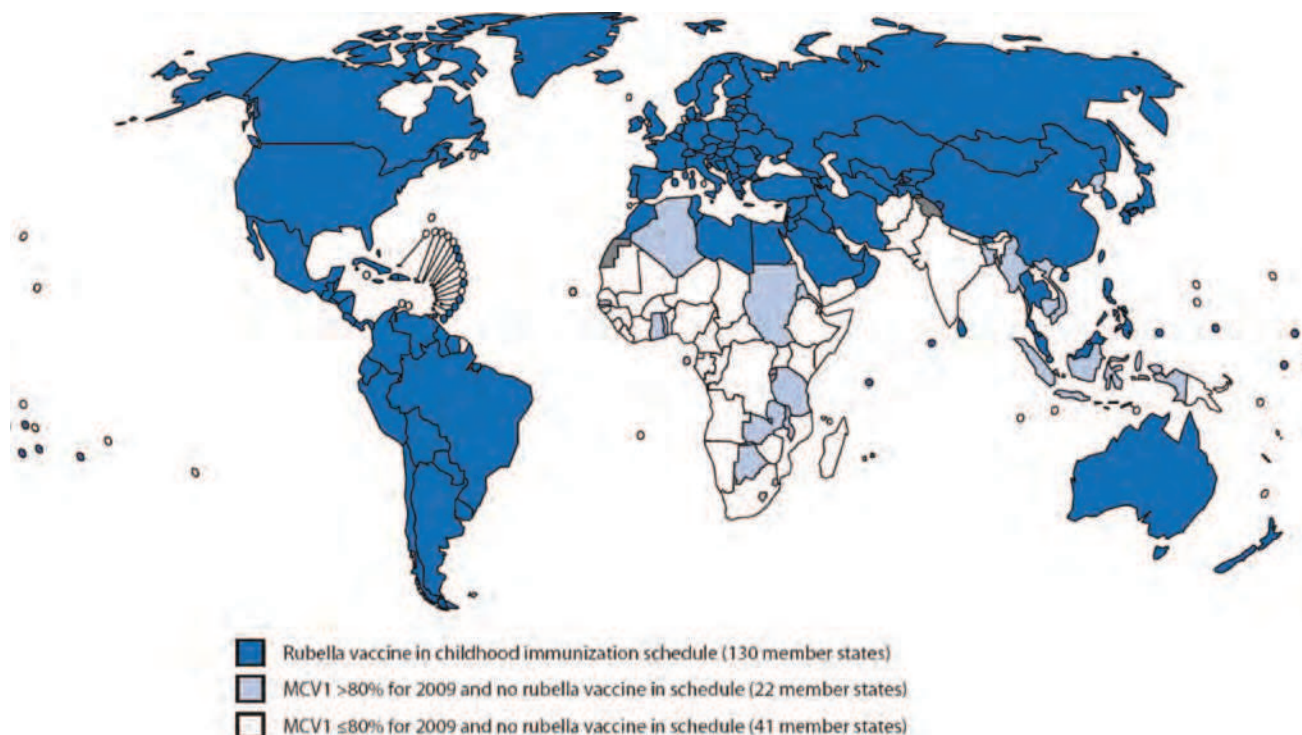

FIGURE 24.1. World map showing countries that have comprehensive rubella vaccination strategies. (From Progress toward control of rubella and prevention of congenital rubella syndrome—worldwide, 2009. *MMWR Morb Mortal Wkly Rep* 2010;59[40]: 1307–1310.)

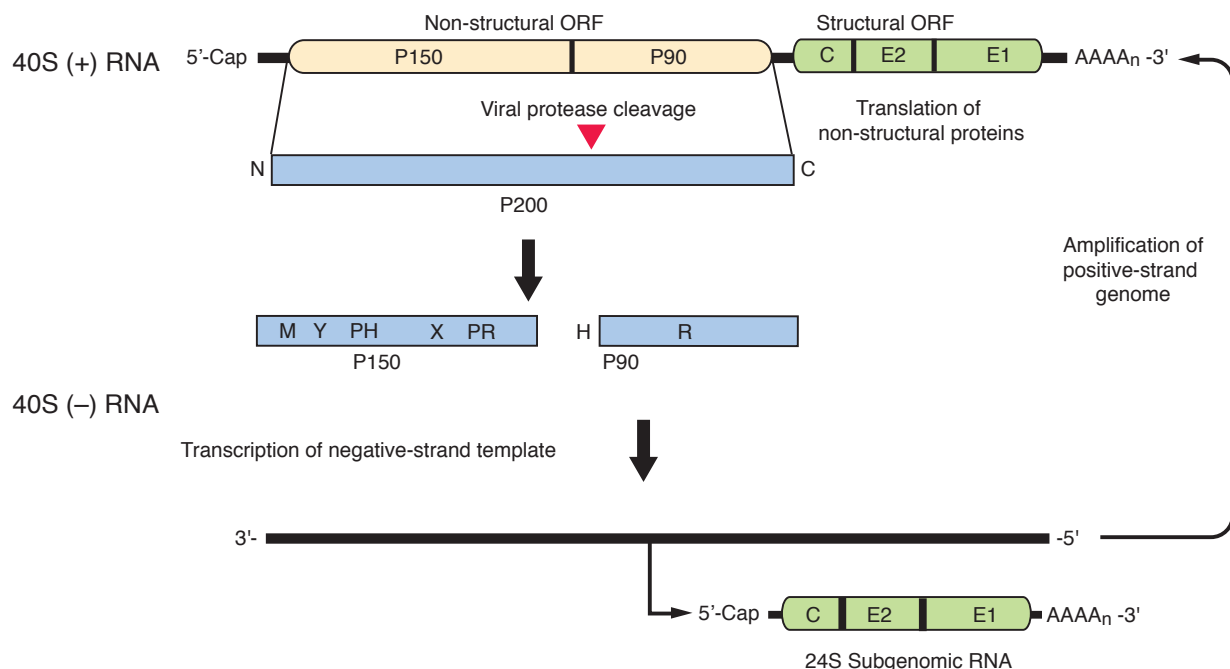

FIGURE 24.2. Organization and expression of the rubella virus (RV) genome. The genome is a single-stranded 40S RNA containing two open reading frames (ORFs). The 5' proximal ORF encodes the nonstructural proteins p150 and p90. The 40S genome serves as a messenger RNA (mRNA) for translation of the nonstructural protein precursor p200, which is cleaved by a virus-encoded protease to produce p150 and p90. The relative positions of methyltransferase (M), Y, proline hinge (PH), X, protease (PR), helicase (H), and RNA-dependent polymerase (R) domains within p150 and p90 proteins are shown. These two proteins form the viral replicase that synthesizes a negative-sense 40S RNA, which then serves as a template for synthesis of more genomic RNA and the 24S subgenomic RNA. Both the 40S and 24S positive-sense RNAs are capped and polyadenylated.

By transmission electron microscopy, RV virions appear as spherical particles with a mean diameter of 61 nm.¹⁶⁰ Virus particles can often be observed budding into the Golgi complex of infected cells (Fig. 24.4). They have an electron-dense nucleocapsid core surrounded by a host-derived envelope.¹⁵⁹ The nucleocapsid (30 to 40 nm in diameter) is composed of a single molecule of genomic RNA and multiple copies of capsid protein. Between the core and the envelope is an electron-lucent region giving the virions the appearance of having a ring or “toga” surrounding the nucleocapsid, from which the name is derived. Virus-encoded glycoprotein spikes project 6 to 8 nm outward from the lipid envelope²³⁶ and denote the virion surface. Early electron microscopic studies suggest that the RV

The buoyant density of rubella virions in sucrose gradients is 1.18 to 1.19 g/mL.¹⁰⁴ In comparison, the buoyant density of alphavirus virions is 1.20 g/mL, a difference that may be attributable to a wider electron-lucent zone between the core and envelope in rubella virions. The reported sedimentation coefficient of RV virions ranges from 240S and 350S.⁹ The reason for this heterogeneity is not known but may be due in part to contamination of the virus preparations by host cell-derived membranous material. The difficulty in obtaining highly purified homogenous preparations of RV virions is one of the numerous technical reasons that has impeded the progress of structural analysis.

FIGURE 24.4. A: Electron micrograph of a rubella virion budding into the lumen of a Golgi cisterna in an infected Vero cell. Note the electron-lucent halo that surrounds the electron-dense nucleocapsid. Bar = 0.5 μm . (Courtesy of Dr. John Law and Ms. Honey Chan). **B: Schematic of a rubella virus (RV) virion.**

The infectivity of RV virions is rapidly lost following exposure to protein denaturing agents (formaldehyde, ethylene oxide, and β -propiolactone) or treatments/reagents that cause lesions in nucleic acids (ultraviolet light or photodynamic dyes). Moreover, because it is an enveloped virus, exposure of RV preparations to nonionic or ionic detergents and lipid solvents abrogates the infectivity of virions.¹⁸¹ Virions are rapidly inactivated by incubation at 56°C for less than 20 minutes, and even at much lower temperatures such as 37°C, RV loses activity slowly ($t_{1/2}$ = 48 hours).¹⁵² When stored at temperatures less than -60°C in the presence of protein stabilizers, RV preparations maintain their infectivity for many years. Fortunately, with respect to vaccine distribution, lyophilized RV preparations are stable for years at 4°C and for months at ambient temperatures.¹⁸⁴

Biological Characteristics

RV has a restricted host range (only humans) *in vivo* but replicates in a wide variety of cultured mammalian cell lines, including primary African green monkey kidney cells, BHK21, RK13, and Vero cell lines. All strains of the virus (including wt+ strains) are slightly temperature sensitive, with higher yields of virus obtained when infected cells are cultured at 35°C rather than at 37°C. The vaccine strains RA27/3 and Cendehill are completely growth restricted at 39°C, while some wt+ isolates are still able to replicate at 41°C, albeit at lower levels.³⁶

In comparison to the rapid lytic infection of mammalian cells by the alphaviruses, RV replicates more slowly, with an eclipse phase of 10 to 12 hours (c.f. 4 hours for Sindbis or

Semliki Forest viruses), and peak titers of secreted virus are not observed until 36 to 48 hours.^{87,242} By comparison, peak viral titers for alphaviruses are observed within 8 hours. As well as exhibiting relatively slow replication kinetics, the amount of infectious virus progeny released per cell is estimated to be 1,000-fold less than for alphaviruses. Under optimal conditions, RV-infected BHK-21 and Vero cells can produce titers of 10^7 and 10^8 plaque-forming units (pfu) per mL, respectively.^{10,241} The relatively feeble replication of RV may be due to a number of factors including low uptake of virus and/or inefficiencies associated with the replicase/transcriptase complex or limitations of the assembly process. For example, RV buds into the Golgi complex, which is a much smaller membrane compartment than the endoplasmic reticulum or the plasma membrane. Another factor that may play a role is the high G + C content of the viral genome (69.5%), which is predicted to form stable secondary and tertiary structures that may impede replication/transcription or translation.⁶⁸ Also related to the G + C content, the codon usage by RV is different from that of mammalian cells, requiring utilization of transfer RNAs (tRNAs) that may be of low abundance, a factor that has been suggested to limit the rate of protein synthesis.²²⁵

Effects on Host Cell

Although RV can have devastating effects on the developing human fetus, infection of most cultured primate or rodent cell lines does not result in major cytopathology. However, in some cell lines (Vero, BHK-21, and RK13), when high multiplicities of infection (MOIs) are employed, the virus causes rounding and detachment of cells commencing at 24 hours postinfection

and increasing over the next 72 hours. Much of the RV-induced cytopathic effect is likely the result of apoptosis.^{61,149,195} Virions that are first inactivated by ultraviolet light do not induce apoptosis, indicating that viral replication is required to cause cell death.^{61,100} The cytopathic determinants of RV have been mapped to the nonstructural genes,¹⁹³ and in agreement with this, expression of RV structural proteins alone in Vero cells does not induce apoptosis.¹⁰⁰ Paradoxically, primary human embryonic fibroblasts seem to be particularly immune to RV-induced apoptosis.³

At low (less than 1) or moderate (1 to 3) MOIs, little virus cytopathic effect is observed in most cultured cells^{61,116} and chronic infections can readily be established (see Replication Strategy section). Induction of apoptosis in response to RV infection is undoubtedly an important antiviral defense mechanism that is employed by cells against many RNA viruses. Because viruses are obligate parasites, they require a living cell for replication. Depending on the apoptotic stimuli, cells can be killed in a matter of hours, a situation that would be seemingly problematic for RV, which has a long eclipse period and whose replication peak occurs between 2 and 4 days postinfection.⁸⁷ However, the maximum RV-induced apoptosis does not occur until after 5 days postinfection,¹⁴⁹ which is consistent with a scenario where the virus actively blocks apoptosis early in infection. Indeed, a recent study revealed that RV-infected cells are highly resistant to apoptotic stimuli.¹⁰⁷ Mapping studies showed that the capsid protein is responsible for this process, which presumably provides a window of opportunity for the virus to replicate before apoptosis is initiated.

In most cell types, cellular macromolecular synthesis on a global level does not appear to be significantly affected, even following high-multiplicity infections (5 to 10 pfu per cell).

For example, host cell RNA synthesis continues normally and protein synthesis is only slightly reduced at 72 hours postinfection in several highly permissive cell lines.⁸⁷ However, in mitogen-stimulated peripheral blood mononuclear cells (PBMCs), host cell protein synthesis was reportedly inhibited by more than 90% at 48 hours postinfection.³⁸ The capsid protein has been shown to block translation *in vitro*,¹⁰⁸ but it has yet to be determined whether this viral protein is responsible for inhibition of protein synthesis in PBMCs or other cell types.

A number of characteristic morphologic changes occur in RV-infected cells. Similar to other togaviruses, RV infection is accompanied by drastic rearrangement of cellular membranes. For example, the endoplasmic reticulum (ER), Golgi complex, and mitochondria are often closely arranged around the virus replication complexes (Fig. 24.5), which are derived from endosomes and/or lysosomes.^{125,127} This arrangement of organelles could in theory facilitate the efficient transfer of virus genome from the site of RNA replication (endosomes) to the area of virus assembly (Golgi complex). Whereas organelle rearrangement is common in togavirus-infected cells, the formation of electron-dense plaques (22 to 25 nm in thickness) between organelles is unique to RV infection.¹²³ The plaques (Fig. 24.6) and associated organelles have been termed confronting membranes or confronting cisternae and commonly involve outer membranes of mitochondria and rough ER, adjacent mitochondria, and adjacent ER membranes, respectively. Expression of capsid protein in the absence of other viral proteins induces mitochondrial clustering and formation of plaques,¹⁵ and immunoelectron microscopy revealed that capsid protein is a major component of the plaques.¹⁰⁹ It has been known for years that a large pool of capsid protein is targeted to the surface

FIGURE 24.5. Electron micrograph of viral replication complex is associated with rough endoplasmic reticulum. Spherules are indicated by arrows. Bar = 0.5 μm . (Courtesy of Dr. John Law and Ms. Honey Chan.)

FIGURE 24.6. Aggregation of mitochondria and formation of electron-dense intermitochondrial plaques in rubella virus (RV)-infected cells. Bar = 0.5 μm . (Courtesy of Dr. John Law and Ms. Honey Chan.)

of mitochondria,^{16,126} and recently it was discovered that capsid affects mitochondrial import.¹⁰⁹ The latter may explain the loss of cristae and dysmorphic (club-shaped) mitochondria in RV-infected cells.¹²² Together, these observations reflect the close link between RV replication and mitochondrial physiology.

Phenotypic Variation

Although there are now recognized to be at least 10 genotypes of RV (Fig. 24.3), there is only one serotype, and infection with one strain provides protection against all others recognized to date. However, the limited genetic differences seen (0.8% to 2.1% at the amino acid level^{221,263}) are associated with differences in hemagglutination,¹³³ plaque morphology,¹¹⁶ temperature sensitivity, virus yield, and cell tropism.³⁶ Compared to natural RV infection, administration of vaccine strains is associated with milder acute symptoms and a lower incidence of complications such as joint and neurological symptoms,^{21,66,229} as well as teratogenic effects.¹³

The major neutralization epitopes appear to be highly conserved among RV strains,^{22,69} although differences have been noted in the kinetics of neutralization⁸¹ and in reactivity to certain monoclonal antibodies.³⁶ However, both infection and immunization are believed to provide protection against all other strains for the duration of the immune response elicited, except in cases where incomplete immunity is induced.²³⁰

The vaccine strains RA27/3 and Cendehill display different tissue tropisms from wt+ strains, including growth restriction in both PBMCs and the B-cell lines, Raji and Cess cells.³⁶ These two strains also show limited replication in cells derived from human joint tissue,¹⁵² with the Cendehill strain completely inhibited in synovial organ cultures and chondrocytes. In comparison, wt+ strains replicate to high titer (10^6 to 10^7 pfu/mL) in joint cells. The determinants that govern growth in joint tissue have been mapped to the 5' end of the genome, which encodes the nonstructural proteins, and as such, it is likely that replication rather than binding and entry events determine tropism.¹³⁵

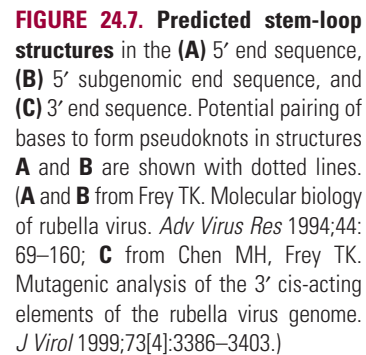

Structure and Organization of the Genome

The genome of RV is a single molecule of positive-strand RNA of approximately 10 kb with a GC content of 69.5%,

by far the highest of any RNA virus sequenced to date.⁶ The 5' end of the RNA has a 7-methyl-guanosine cap,¹⁶⁶ while at the 3' end there is a poly (A) tract with a mean length of 53 nucleotides.²⁴⁶ The genome consists of two nonoverlapping polycistronic open reading frames (ORFs) separated by a nontranslated region of 123 nucleotides (Fig. 24.2).¹⁹² The 5' proximal ORF (approximately 6,385 nucleotides) encodes the nonstructural proteins, while the 3' proximal ORF (3,189 nucleotides) encodes the three structural proteins, capsid, E2, and E1. The structural proteins are translated from a 5' capped and polyadenylated subgenomic RNA that is collinear with the 3' one-third of the 40S genome.¹⁶⁶ The complete nucleotide sequences have been determined for the genomes of several wild-type and vaccine strains of RV⁶⁸ and are available in GenBank. In addition, infectious complementary DNA (cDNA) clones of several strains have been produced and used to map genetic elements involved in viral replication and attenuation.^{135,196,246,259}

Cis-Acting Elements

The availability of infectious RV cDNA clones^{135,196,259} and replicons²³⁷ has enabled the application of reverse genetics to study the roles of *cis*-acting elements in genome replication. Both the 5' and 3' untranslated regions (UTRs) of the RV genome are believed to form secondary structures that influence transcription and translation events. For example, the predicted 5' stem-loop (5'SL), which encompasses nucleotides 15 to 65, has a terminal loop as well as a bulge in the stem and a hinge region (Fig. 24.7). It is believed to form a pseudoknot,¹⁹⁴ a structure that has been shown in a number of plant and animal viruses to enhance binding of proteins that function in RNA replication.^{57,110} Within the single-stranded leader sequence (nucleotides 1 to 14) and the stem-loop, there are three AUG codons starting at nucleotides 3, 41, and 57. Translation of the long ORF encoding the nonstructural genes is initiated at AUG₄₁, while the first and third AUGs are in a different reading frame and are terminated at nucleotides 54 and 90, respectively. Indeed, site-specific mutagenesis studies suggest that AUG₃ is not essential for viral replication,¹⁹⁴ nor is it known whether short peptides that originate from either AUG₃ or AUG₅₇ play any role in virus biology. However, it is notable that the

Between the nonstructural and structural genes is a 123-bp region that is predicted to form a series of stem-loops

(Fig. 24.7). This region shares 58% identity with the equivalent region in the Sindbis virus genome and may be important for regulating synthesis of the subgenomic RNA. In addition, translation of the structural genes is affected by mutations in this region, which forms the 5' end of the subgenomic RNA.¹⁸⁰ In the 3' UTR, there is a stretch of 59 nucleotides following the stop codon at nucleotide 9701. A complex secondary structure involving three major stem-loop structures⁴³ has been predicted for the 3' terminal 240 nucleotides (Fig. 24.7).

These 3' UTR sequences function in *cis* to regulate transcription, specifically, synthesis of plus-strand viral RNAs but not negative-sense RNA.⁴⁴

Encapsidation Signal

Mapping studies revealed that capsid protein binds with relatively high affinity to a 29-nucleotide segment located in the 5' nonstructural gene region between nucleotides 347 and 375.¹³²

Nonstructural ORF and Protein Products

The nonstructural (NS) genes are located in the 5' end of the viral genome within a long ORF commencing at AUG.⁴¹ The NS ORF is translated as a single polypeptide greater than 200 kD that is cleaved into two products, p150 and p90,¹⁴⁰ that function in replication and transcription of viral RNAs (Fig. 24.2). The gene order of the 5' ORF is NH₂-p150-p90-COOH. The two nonstructural proteins have several enzymatic activities including RNA polymerase, protease, and helicase and together form the viral replicase. Proteolytic processing of the p200 polypeptide marks the switch from synthesis of negative-strand genomic RNA to synthesis of plus-strand RNA.¹²⁸

p150 contains several domains that are conserved among other RNA virus-encoded proteins. A protease domain located in the carboxyl portion of p150 (Fig. 24.2) is responsible for cleavage of the nonstructural precursor protein p200 and is critical for virus replication.^{42,260} Mutagenesis studies have shown that the RV protease is a metalloprotease that requires divalent cations for activity^{130,131} and functions in both *cis* and *trans* modes.¹²⁹ A putative methyltransferase domain in the amino terminus is believed to have a role in capping the viral RNA.²¹¹ p150 also contains an X domain that has homology to the nonstructural proteins of alphaviruses, coronaviruses, and hepatitis E virus.⁸⁰ The function of the X domain is not well characterized, but it is required for *trans* cleavage by the RV protease and in alphaviruses at least is important for replication.⁸⁶ Interestingly, the X domain is the region that is most highly conserved between RV and alphaviruses.⁶⁰ Two other domains of unknown function, Y and a proline hinge, are also present in p150. The order of these domains in p150 is NH₂-methyltransferase-Y domain-proline hinge domain-X domain-protease-COOH. The second nonstructural protein, p90, comprises 905 amino acid residues and contains the replicase and helicase motifs. Based on comparison with global RNA-dependent RNA polymerase consensus sequences,¹¹¹ the GDD tripeptide at amino acids 1965 to 1967 of p90 is the active site of the RV replicase. An RNA-stimulated nucleoside triphosphatase (NTPase) that promotes unwinding of the template during RNA replication is associated with the helicase motif.⁸⁵

The localization of RV nonstructural proteins, p150 and p90, is less well studied than that of the structural proteins. This is because the nonstructural proteins are present at relatively low concentrations in infected cells, and furthermore, attempts to produce useful antibodies against these antigens has met with limited success. However, it has been reported that p150 associates with long tubular structures that correspond to sites of viral RNA synthesis.¹¹⁸ p90 has been detected in discrete cytoplasmic puncta that form linear chains.⁵ The identity of the p90-associated structures was not determined, but it is likely that they are replication complexes derived from endocytic vacuoles. Presumably, a large pool of p150 is also

localized to the p90-positive foci. No information regarding sequences that target the nonstructural proteins to endocytic membranes has been reported.

Structural ORF and Protein Products

The structural genes are contained within the 3' ORF of the 40S genomic RNA; however, they are actually translated from a subgenomic 24S RNA that is produced in infected cells. There are two in-frame AUG initiation codons in the subgenomic RNA separated by 21 nucleotides. The downstream AUG is in the more favorable context for translation initiation, but *in vitro* mutagenesis experiments indicate that both codons can be used.⁴⁷ The 24S subgenomic RNA encodes three structural proteins, which are translated in the order NH₂-C-E2-E1-COOH.¹⁶⁵ Unlike alphavirus structural proteins, which require both host cell signal peptidase and a capsid-associated protease for complete processing,¹⁵⁰ processing of the RV structural polypeptide (Fig. 24.8) into C, E2, and E1 only requires signal peptidase, which is encoded by the host cell.^{139,224}

In the absence of genomic RNA, coordinated expression of the RV structural proteins in mammalian cells results in the assembly and secretion of rubella virus-like particles (VLPs).^{94,199} The VLPs, which resemble native virions in terms of morphology and antigenicity, have served as a useful tool for studying virus assembly, and as a consequence, the roles of RV structural proteins and their domains in the assembly process are relatively well understood. The fact that rubella VLPs are efficiently assembled and secreted in the absence of genomic RNA indicates that virus budding is not tightly linked to nucleocapsid assembly.

Capsid

The capsid protein is a phosphoprotein with an apparent molecular mass of 33 to 35 kD.¹³⁹ The protein contains 300 amino acid residues and is rich in arginine and proline residues, particularly at its amino terminus, which gives it a net positive charge⁴⁶ and facilitates its interaction with genomic RNA during nucleocapsid formation. Capsid protein often migrates as a doublet on SDS-PAGE gels. The reason for this remains unknown, but it is not due to the use of an alternate translation start site.^{47,139} Virion-associated capsid protein can be isolated as disulfide-linked dimers, but intermolecular disulfide bonding is not necessary for formation of virus particles.^{12,124}

Cleavage of the RV capsid protein from the polypeptide precursor is distinct from that of alphavirus capsid proteins, which contains an autoprotease that separates the capsid protein from the polypeptide.¹⁵⁰ As a consequence, alphavirus capsids are free in the cytoplasm of infected cells. RV capsid protein, in contrast, lacks autoprotease activity, and separation from E2 is carried out by host cell signal peptidase.⁴⁶ The E2 signal peptide is therefore retained as the carboxyl terminus of capsid protein (Fig. 24.8), where it serves to confer membrane association of the protein.^{91,139,224} The membrane association of RV capsid protein is unique among togaviruses and may account for some of the unusual morphogenetic features of the virus. For example, retention of the E2 signal peptide on capsid protein is necessary for assembly of VLPs and presumably infectious virions.¹²⁰

Role of the Capsid Protein in Virus Assembly. The primary function of capsid protein during virus assembly is to homo-oligomerize and bind viral genomic RNA to form

FIGURE 24.8. Processing of rubella virus (RV) structural proteins. The 24S RNA serves as the messenger RNA (mRNA) for translation of a structural polyprotein precursor, which is then cleaved by host signal peptidase to produce capsid, E2 and E1. The relative membrane orientations of the structural proteins immediately following translocation into the endoplasmic reticulum (ER) are shown. The amino (N) and carboxyl (C) termini of the proteins are indicated.

the nucleocapsid. The RNA-binding domain of capsid protein resides within amino acid residues 28 to 56 and binds to a packaging signal (nucleotides 347 to 375) in the genomic RNA.¹³² Posttranslational modification of capsid protein may play an important role in regulating the formation of nucleocapsids because phosphorylation of serine 46 within the RNA-binding domain negatively regulates RNA binding.^{119,121} This is believed to prevent nonspecific binding of cellular RNAs to capsid protein and to delay binding of genomic RNA until the virion components are targeted to the budding site. *In vitro*, capsid protein is a substrate for protein phosphatase 1A, an enzyme that has been implicated in Golgi-associated functions.¹²¹ Accordingly, targeting of capsid protein to the Golgi complex, followed by dephosphorylation at this site, could explain how nucleocapsid assembly is synchronized with virus assembly (Fig. 24.9). Supporting this scenario is the observation that virion-associated capsid protein has a higher affinity for viral RNA and contains significantly less phosphate than cell-associated capsid protein.^{119,121} Similar to alphaviruses,²²³ it is thought that capsid protein drives budding of RV through interactions with the envelope glycoproteins; however, direct binding between RV capsid protein and E2 and/or E1 has yet to be demonstrated.

Nonstructural Roles of the Capsid Protein. In addition to nucleocapsid assembly, the RV capsid protein plays a role in regulating viral transcription and replication. The first indication of this nonstructural function came from the observation that expression of capsid protein rescues the replication of an RV replicon containing an in-frame deletion of p150.²³⁸ Further analyses indicated that the capsid protein is involved in modulating viral genomic and subgenomic RNA synthesis.²³⁹ In the absence of capsid protein expression, the ratio of genomic RNA to subgenomic RNA is substantially lower. It is believed that a pool of capsid protein that associates with the replication complexes is responsible for regulating synthesis of viral RNAs. Interestingly, the effects of capsid protein on transcription depend on the levels of replicon RNA.⁴⁵ At low levels of RNA, capsid protein expression enhances replication of viral RNA, but with higher levels of RNA, capsid protein is inhibitory for this process.

Given its multiple roles, it is not surprising that the RV capsid protein is associated with multiple organelles. Consistent with its function in virus assembly, pools of capsid protein are localized to the Golgi.^{11,94} Transport of capsid to the Golgi region from the site of its synthesis, the ER, depends on E1 and E2.^{74,120} Capsid also localizes to mitochondria and to virus

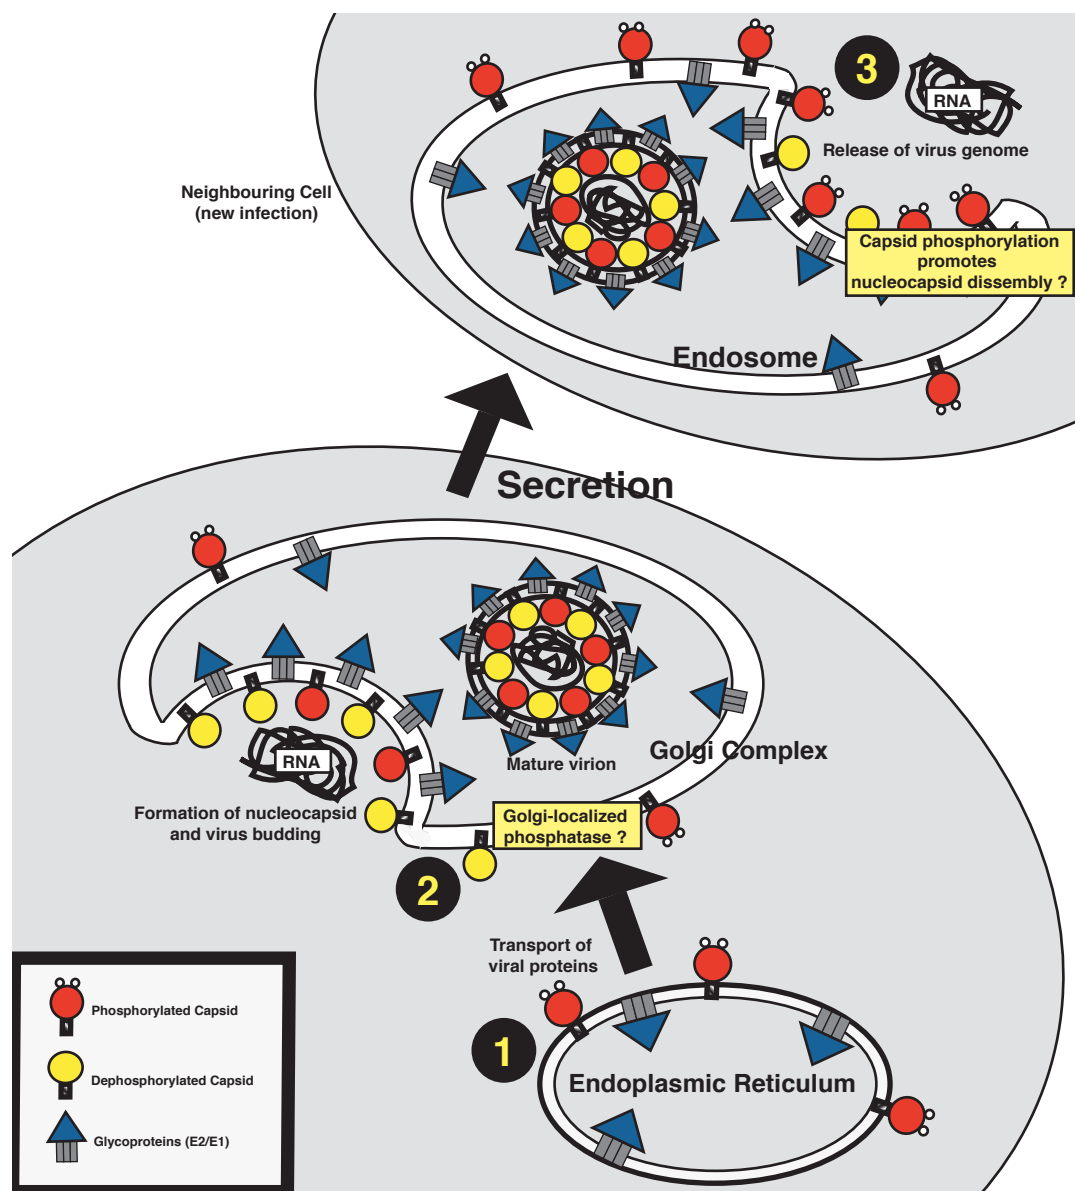

FIGURE 24.9. Model to illustrate the putative roles of dynamic phosphorylation of capsid protein in virus replication. **1:** Phosphorylation of newly synthesized capsid protein prevents nonspecific binding of RNA and premature formation of nucleocapsid at the early stages of virus assembly. **2:** Capsid protein is subsequently targeted to the Golgi complex and dephosphorylation of the protein at this stage allows interaction with the genomic RNA, formation of the nucleocapsid, and subsequent virus budding. **3:** Timely rephosphorylation of capsid protein before or during virus entry promotes the disassembly of nucleocapsid.

replication complexes.^{16,123} In contrast, the glycoproteins E1 and E2 are targeted only to the virus budding site (Golgi), suggesting that they do not have major nonstructural roles. Together with p150, replication complex–localized capsid protein¹¹⁸ is thought to modulate replication of viral RNA, whereas the mitochondrial pool of capsid plays one or more critical roles in virus–host interactions (Fig. 24.10). For example, it potently blocks apoptosis by sequestering the proapoptotic host protein Bax into nonfunctional complexes.¹⁰⁷ RV capsid also interferes with mitochondrial import,¹⁰⁹ a critical process that is linked to apoptosis in mammalian cells.¹⁸³ Finally, it has been known for

more than a decade that capsid interacts with the mitochondrial matrix protein p32.¹⁶ The precise function of this interaction is not clear, but several lines of evidence suggest that it is important for virus replication. First, ablation of the p32-binding site in capsid protein reduces the replication efficiency of RV by 1,000-fold.¹⁵ Second, depletion of cellular p32 pools by RNA interference results in a 10-fold reduction in virus replication.⁴⁹ Capsid protein–p32 interactions may also be important for synthesis of subgenomic RNA and/or translation of structural proteins. Finally, loss of stable binding between capsid protein and p32 is correlated with reduced mitochondrial clustering in

FIGURE 24.10. Integrated model of rubella virus (RV) capsid nonstructural functions. At the replication complex, capsid associates with nonstructural proteins (p150 and p90) and regulates transcription and replication of viral RNA. Late in the infection cycle, local sequestration of translation initiation factors such as poly(A) binding protein (PABP) may modulate the switch from translation to packaging of the genomic RNA, a mechanism that would leave the viral RNA available for packaging into nucleocapsids at the Golgi complex. Capsid prevents apoptosis by binding to Bax and inducing the formation of heterooligomers that are incompetent for pore formation at the mitochondria and potentially at the endoplasmic reticulum (ER) membranes. Capsid may also inhibit apoptosis by preventing translocation of pro-apoptotic proteins such as p32 into the mitochondria or by engaging in complexes with the mitochondrial lipid, cardiolipin. (Modified from Ilkow CS, Willows SD, Hobman TC. Rubella virus capsid protein: a small protein with big functions. *Future Microbiol* 2010;5[4]:571–584.)

the perinuclear region. Together, these results suggest that interactions between capsid protein and p32 are important for RV-induced rearrangement of mitochondria, a phenomenon that is associated with optimal replication.

ENVELOPE PROTEINS

E1 and E2 are type I membrane proteins that dimerize to form the spike complexes on the surface of the virion (Fig. 24.8). The major functions of these spikes are to bind receptors on the host cell and to mediate fusion with cell membranes.¹¹⁴ The envelope proteins, E1 in particular, are the major antigenic determinants against which neutralizing antibodies are directed.²⁴⁹

E1 is 481 amino acid residues in length and exhibits an apparent molecular mass of 58 kD when analyzed by SDS-PAGE. The mature protein contains three asparagine-linked oligosaccharide moieties.⁹⁵ An amino terminal signal peptide facilitates translocation of E1 into the ER and a 22-amino acid hydrophobic sequence at its carboxyl terminus mediates membrane association.⁹⁶ E1 also contains a carboxyl terminal tail of 13 amino acid residues that is exposed to the cytoplasm. E2 (282 amino acids residues) contains two stretches of hydrophobic amino acid residues near its carboxy terminus,

an 18-amino acid residue transmembrane domain, and the E1 signal peptide.^{11,46} These two hydrophobic domains are separated by a 7-amino acid residue loop that is rich in basic amino acid residues. Similar to E1, translocation of E2 into ER membranes is mediated by an amino terminal signal peptide.⁹¹ E2 is heavily glycosylated and contains both asparagine-linked and O-linked carbohydrates.^{96,136} Finally, both glycoproteins are modified by the addition of palmitate prior to virus assembly.^{93,249} The role of this modification in spike protein function has not been investigated, but it is possible that acylation may serve to further stabilize and/or orientate E2 and E1 in the membrane. The membrane orientations of the RV structural proteins are shown in Figure 28.8.

Replication Strategy

The replication strategy of RV is similar to that of alphaviruses in many respects, but there are several quantitative and qualitative differences. As discussed previously, RV replication is less robust and much slower than that of alphaviruses.⁸⁷ In addition, it is not possible to obtain a uniformly infected population of cells within 24 hours, even at high multiplicities of infection.²¹⁴ The reason for this phenomenon is not clear, but

FIGURE 24.11. Entry and exit strategy of rubella virus (RV). 1: Uptake of RV is dependent upon receptor-mediated endocytosis. The low pH of the endosome/lysosome induces virus uncoating. 2: RNA replication occurs at the cytopathic vacuoles that originate from endosomes/lysosomes. Genome amplification and synthesis of the 24S subgenomic RNA also occurs at these sites. 3: Synthesis of structural proteins takes place at the endoplasmic reticulum and processing by the host cell signal peptidase separates the polyprotein into individual structural proteins. Subsequently, the structural proteins assemble and are transported to the Golgi complex. 4: Nucleocapsid assembly and virus budding occur at the Golgi complex. 5: Rubella virions undergo a series of maturation events before exocytosis.

given the fact that eventually all cells within a permissive culture become infected, it is possible that a cell cycle-dependent factor is required for RV entry or early viral replication events. Another major difference from the alphaviruses is that a large pool of the nascent RV capsid protein remains membrane associated.^{120,224} This may be one of the reasons that RV nucleocapsid assembly differs from that of alphaviruses, which are not membrane associated. Free nucleocapsids are rarely observed in RV-infected cells but rather assembly is coincident with virus budding at the Golgi complex, a process that is hypothesized to be regulated by reversible phosphorylation of the capsid protein.¹²¹ A schematic diagram of how RV enters, replicates, and exits from host cells is shown in Figure 24.11.

Virus Entry

Host cell–encoded proteins and lipids are important for virion binding,^{50,142} after which the virus is internalized by receptor-mediated endocytosis.¹⁸⁶ At low pH, the envelope glycoproteins become fusogenic, and capsid undergoes a conformational change and becomes hydrophobic,^{114,145} indicating that the acidic environment within endosomes induces fusion of the viral envelope with cellular membranes followed by release of genomic RNA from the nucleocapsid. The type I membrane protein myelin oligodendrocyte glycoprotein binds to the E1 glycoprotein and was recently identified as a host receptor for RV.⁵⁰ This protein is most highly expressed in the central nervous system, but in epithelial and lymphoid cells, which serve as the portals

of entry and initial sites of replication, myelin oligodendrocyte glycoprotein levels are much lower. As such, it cannot be ruled out that the virus uses different receptors in different cell types.

Replication Complexes

Similar to all other plus-strand RNA viruses that infect mammalian cells, replication of RV RNA occurs in association with cellular membranes. Cytoplasmic vacuoles (Fig. 24.5) with regularly shaped invaginations or spherules (60 nm in diameter) are observed in RV-infected cells.¹²⁷ The spherules are connected to the vacuolar membranes by thin membranous necks and can be stained with antibodies against p150 and double-stranded RNA, suggesting that they are the sites of viral RNA synthesis.^{118,125} These vacuoles also co-localize with lysosomal markers, indicating that they are derived from endosomes and/or possibly lysosomes.¹³⁸

Recently, replication complexes in RV-infected cells have been analyzed using electron microscopy and freeze fracture techniques.⁶⁴ Replication of viral RNA occurs within protected membranous pockets of the cytopathic vacuoles. The vacuoles are surrounded by rough ER, an arrangement that may facilitate binding between RNA and the capsid protein (which is synthesized on the surface of the ER) to promote nucleocapsid formation. In a number of fundamental aspects, RV replication complexes are similar to those found in alphavirus-infected cells.⁷¹ However, there are several important distinctions between them. First, assembled nucleocapsids are rarely

observed near replication complexes in RV-infected cells. In contrast, nucleocapsids are regularly observed surrounding the replication complexes of alphavirus-infected cells. In RV-infected cells, formation of the replication complexes coincides with the rearrangement of other cellular structures. Specifically, rough ER and Golgi are in close proximity to the virus-modified endocytic organelles, and mitochondria cluster to regions of the cell containing replication complexes.^{123,127} Although mitochondrial aggregation in the vicinity of replication complexes also occurs in alphavirus-infected cells, the close association of the rough ER and Golgi with replication complexes is unique to RV-infected cells. Recruitment of ER and Golgi membranes to the replication complexes may be necessary to coordinate translation of the structural proteins and packaging of the genomic RNA. Mitochondria are also recruited to the replication complexes, but the reason for this is not clear. It has been suggested that this arrangement of organelles would increase the availability of adenosine triphosphate (ATP) for virus replication, but solid evidence to support this theory is lacking.

Targeting of Structural Proteins to the Budding Site

Following synthesis of the subgenomic RNA, the RV structural proteins are translated in association with ER membranes. The structural polyprotein precursor is cleaved by signal peptidase at two sites (Fig. 24.8) to generate the three structural proteins.^{91,96} The structural proteins are then posttranslationally modified and transported to the Golgi complex, which is the primary site of virus budding. Processing and transport of the RV structural proteins have been extensively studied using transfection experiments. When co-expressed, E2 and E1 heterodimerize, form intramolecular disulfide bonds in the ER, and are transported to and retained in the Golgi.^{11,99} Targeting of the virus glycoproteins to the Golgi complex is independent of capsid, indicating that accumulation of E2 and E1 in this organelle is the major factor in determining the budding site. In the absence of E2, E1 does not target to the Golgi but rather is retained in a smooth ER compartment.⁹⁸ The membrane proximal regions of the structural proteins have important roles in regulating the localization and transport of these proteins. For example, within the transmembrane and the cytoplasmic domains of E1 resides an ER retention signal that prevents or delays transport of nascent viral glycoproteins from the ER.⁹² Co-expression of E2 appears to mask the ER retention signal in E1, thereby allowing transport of the E2-E1 heterocomplex from the ER to the Golgi after a maturation period. The transmembrane domain of E2, in turn, contains a retention signal that mediates retention of the E2-E1 heterodimer in the Golgi.⁹⁷

The highly regulated transport of RV glycoproteins may serve as a quality control mechanism to ensure only properly assembled subunits reach the virus budding site. The half-life for transport of the RV glycoproteins to the Golgi is 60 to 90 minutes (whereas for alphavirus glycoproteins it is approximately 25 minutes).⁹⁰ Dimerization of E1 and E2 in the ER is not rate limiting as evidenced by the fact that these two proteins associate rapidly following synthesis. E2 achieves its mature conformation shortly after synthesis and has been proposed to function as a scaffold for E1. Accordingly, the rate-limiting step for transport of the glycoproteins is the relatively slow maturation and folding of E1 in the ER.⁹⁹ The mature ectodomain of E1 contains 20 cysteine residues that participate in the formation of intramolecular disulfide bonds.⁸⁴ It is hypothesized

that the ER retention signal in E1 is required to retain nascent E1 in the ER until it has achieved the proper conformation, which includes the formation of intramolecular disulfide bonds. Indeed, replacing the E1 transmembrane domain with analogous domains from other membrane glycoproteins actually increases the rate of ER-to-Golgi transport for E1 and E2.⁷⁴ The E2 transmembrane and cytoplasmic domains are required for assembly of E2-E1 heterodimers and therefore have an indirect role in regulating transport of the RV glycoproteins from the ER to the Golgi. Finally, mutagenesis studies have shown that N-linked glycosylation is important for maturation and intracellular transport of both E1 and E2 glycoproteins.^{95,198}

As well as regulating targeting of E1 to the Golgi complex, E2 is required for transport of the capsid protein to the intracellular budding site.^{11,94} The carboxyl terminus of E2, which includes the transmembrane and cytoplasmic domains, is essential for this process⁷⁴ and formation of VLPs¹²⁰ and likely infectious virions. Lateral interactions between the E2 signal peptide and the transmembrane regions of E2 and/or E1 may facilitate transport of capsid from the ER to the Golgi by incorporation into ER-derived transport vesicles. In contrast, the analogous regions of E1 are not required for localization of capsid to the juxtannuclear region. Together, these results indicate that the E2 carboxyl terminus governs the targeting of all three RV structural proteins to the virus budding site.

Virus Assembly and Secretion

RV budding has been reported to occur at both the Golgi complex and the plasma membrane, depending on cell type and the time postinfection.^{10,244} However, several lines of evidence suggest that the primary site for virus budding is the Golgi complex. First, the presence of a signal in E2 mediates retention of the structural proteins in the Golgi complex, and consequently, only a small fraction of the RV structural proteins reaches the plasma membrane.^{97,99} Second, budding at the plasma membrane reportedly occurs late in infection, suggesting that this is not the principal budding site. Furthermore, virion membrane composition is more similar to that of intracellular membranes rather than the plasma membrane.⁸

Unlike alphavirus nucleocapsids, which are formed in the cytoplasm of infected cells prior to budding, RV nucleocapsids form in association with cellular membranes coincident with budding and are rarely observed in the cytoplasm of infected cells.¹²⁶ It has also been hypothesized that RV employs a mechanism to prevent premature assembly of nucleocapsids (Fig. 24.9). Specifically, reversible phosphorylation of the RNA-binding region of capsid may regulate assembly and disassembly of RV nucleocapsids.^{119,121} Whether phosphorylation of capsid proteins has any role in assembly of alphavirus nucleocapsids has not been investigated.

The mechanisms that regulate interactions between the nucleocapsid and spike glycoproteins during virus budding are largely unknown. With respect to the budding reaction, it is tempting to speculate that electrostatic interactions between the cytoplasmic domain of E2, which is rich in basic amino acid residues, and clusters of acidic amino acid residues in the capsid are involved. Indeed, nonconservative mutations in this E2 domain drastically affect the assembly of VLPs.⁷⁴ It is also well established that the transmembrane domains of the structural proteins are important for targeting to the budding site. In this respect, lateral interactions between the transmembrane

domains of E1, E2, and capsid protein may be important for the budding reaction. Finally, it is important to consider that interactions between RV structural proteins and host cell proteins contribute to efficient budding of virus particles.

A morphologic study that employed freeze-substitution electron microscopy revealed that rubella virions undergo a maturation process following budding into the Golgi.²⁰⁶ Specifically, at early time points, intra-Golgi virions exhibited homogenous interiors with fine contacts between the core and the particle membrane. At later time points the virion cores appeared denser and were smaller in diameter such that they were clearly delineated from the virion membrane. These results indicate that the virion maturation process involves compaction of the nucleocapsid. Several lines of evidence suggest that the E1 transmembrane and cytoplasmic domains also function in virion maturation and/or secretion. Replacement of the E1 transmembrane domain does not affect budding of VLPs in the Golgi, but secretion of the particles into the extracellular space is blocked.⁷³ Similarly, introduction of point mutations into the E1 transmembrane and/or cytoplasmic domains drastically reduces virus secretion without affecting the assembly process at the Golgi.^{200,259} These rather surprising data indicate that virus assembly at the Golgi complex is not coupled to secretion and that E1 is involved in a late-stage maturation event that is necessary for virus secretion.

There is limited information regarding the interactions between RV virions and polarized cells. Because it causes a systemic infection, the virus must cross one or more epithelial layers, including the upper respiratory epithelium. Cultured epithelial cells can be infected from the apical and basal membranes, indicating that RV receptors are not confined to one surface.⁷³ The secretion of virus particles varies according to cell type. In two of the three polarized cell lines examined, virions were released primarily from the apical surface, but significant quantities were also secreted from the basolateral membrane. Presumably, secretion of rubella virions from the apical surface facilitates virus spread from person to person, whereas basolateral secretion could be important for establishing a systemic infection and/or crossing the placenta prior to fetal infection.

RV Persistence

Although cell death by apoptosis occurs in highly susceptible cell lines infected at high MOIs, infection of a wide variety of cells *in vitro* with low MOIs results in little cytopathology and viral persistence.^{1,3,70,255} In fact, a recent study has shown that RV-infected cells are quite resistant to a variety of apoptotic stimuli as a result of interaction between the capsid protein and the host protein Bax.¹⁰⁷ These findings are consistent with earlier observations that while temperature-sensitive mutants and defective interfering (DI) particles develop in and may play a role in controlling replication in persistently infected cells, neither is required to establish persistent infection.^{70,255} During long-term persistence in RV-infected Vero cells, DI RNAs become the dominant species of viral RNA, with genomic RNA decreasing to low levels. Persistence in cultured cells is thus a chronic infection, with the majority of cells expressing viral antigen and RNA, much of which is DI RNA. These cultures release low levels of temperature-sensitive progeny virus and DI particles. Finally, while it cannot be ruled out that interferons play a role in viral persistence, they are clearly not essential because persistent RV infections can be established

in interferon-deficient cell lines such as Vero and BHK-21 cells.²²² Moreover, exogenous interferon was not found to have an effect on RV persistence in these cell lines.

The virus can persist for many months in congenitally infected human fetuses, and multiple organ systems are affected (see Mechanisms of Teratogenesis section). Following postnatal infection, PBMCs are an established site of RV persistence *in vivo*, particularly in adults who develop rubella-associated arthritis following natural infection or immunization.³⁵ Viral persistence *in vivo* occurs in the presence of high levels of neutralizing antibody, which not only may limit viral spread but also has been suggested to actually promote viral persistence. To date, however, this theory has yet to be substantiated. Another site of persistence *in vivo* is joint tissue,^{39,67} which has led to speculation that RV plays a role in development of degenerative joint disease (see Complications section).

In vitro, both wt+ and vaccine strains of RV can infect and persist in chondrocyte-derived cell lines³⁶ and in primary cultures of human joint tissue.¹⁵² Except for the Cendehill vaccine strain, all other RV strains can replicate and persist in joint tissue for more than 3 months. Interestingly, virus derived from these chronically infected cultures was temperature sensitive, but no DI particles were detected.

Animal Models of Rubella Virus Infection

There are no reliable animal models for the study of clinically symptomatic rubella infection. However, a variety of laboratory animals (including nonhuman primates) can be asymptomatically infected with RV. For example, rhesus and African green monkeys develop viremia, shed virus in respiratory secretions, and produce humoral immune responses in a manner that is similar to acute rubella in humans.¹⁰¹ However, attempts to model the teratogenic effects of rubella in various animals, including baboons, cynomolgus monkeys, marmosets, and rats, have produced inconsistent results with, at best, low incidence of defects such as cataracts or stillbirths.^{248,251} Infection of the central nervous system (CNS) has been shown to occur in immunosuppressed BALB/c mice, and as such, it is possible that this system could work as a small animal model to understand the effects of RV on the brain.¹⁴¹ Unfortunately, none of the animal systems has proven sufficiently reliable to study details of the pathogenesis of either acquired or congenital rubella.

Antigenic Composition and Determinants

Complement-Fixing and Hemagglutinating Antigens

Early serologic tests for rubella used crude complement fixation antigens extracted from virus-infected cells and purified on sucrose gradients. A more slowly sedimenting fraction from the gradients with a density of 1.08 to 1.10 in sucrose (as compared to a density of 1.18 to 1.20 for intact virions) was shown to have hemagglutinating (HA) activity.²³⁶ HA activity is also associated with cell-free virus preparations¹⁰⁵ and can be extracted from infected cells or supernatant virus using Tween 80 and ether, resulting in a 26S particle that retains biological activity. By electron microscopy, it appears as a 15-nm rosette with a hollow core.²³⁵

B-Cell Epitopes

The E1 glycoprotein is the immunodominant surface molecule of the virus particle as evidenced by the fact that it is the major target for the host's humoral immune system.²⁵⁶ Antibodies to

both E2 and capsid are also found in humans, although at lower levels and of lower avidity. Mapping of antigenic domains on the viral proteins was first carried out using monoclonal antibodies.²⁵⁶ Later, detailed studies on the fine antigenic structure of each viral protein were carried out using recombinant proteins, proteolytic peptide fragments, and synthetic peptides to deduce antigenic sites.^{40,147,154} At least five distinct nonoverlapping immunoreactive regions were identified in the E1 protein (E1_{11–39}, E1_{154–179}, E1_{199–239}, E1_{226–277}, and E1_{389–412}). Cellular proliferative responses to these peptides were found in 29% to 83% of the subjects tested,¹⁵⁴ including one peptide (E1_{208–239}) that contained a previously identified neutralization domain.²⁵⁷ Reactivity with this peptide in an enzyme-linked immunoassay (ELISA) correlates well with assays that measure hemagglutination inhibition (HAI) and virus neutralization.^{54,157} To date, two B-cell epitopes have been identified on the capsid protein, C_{1–30} and C_{96–123}, and one (E2_{31–105}) on the E2 glycoprotein.^{40,147,173}

T-Cell Epitopes

There are at least 17 RV-specific T-cell epitopes, but the precise limit of each epitope is not known.^{147,154,172} A minimum of four immunodominant sites are located on E1, and these display reactivity to T cells from several donors with different HLA haplotype backgrounds.¹⁷⁸ Subsequently, minimal T-helper-cell epitopes were identified at E1_{280–287}, E1_{385–393}, and E1_{410–420} using T-cell lines from seropositive healthy donors, with variation in responsiveness found between individuals.¹⁴¹ Interestingly, binding of the peptide E1_{272–285} to HLA-DR and its recognition by RV-specific clones is influenced by DR β polymorphisms.¹⁷⁷

At least three T-cell epitopes have been found on the E2 protein.^{154,172} One of these peptides (E2_{54–65}) is present in approximately 50% of T-cell lines derived from donors with the HLA-DR7 phenotype.¹⁷⁰ With respect to the capsid protein, a peptide (C_{265–273}) is recognized by T-cell clones derived from donors expressing the DRB1*0403 and DRB1*0901 alleles.¹⁷¹ However, this peptide is recognized promiscuously by HLA-DR molecules that have common residues in pocket 4 of the peptide-binding groove and therefore likely defines a DR supertype.¹⁷⁶

EPIDEMIOLOGY

Incidence

Prior to the introduction of immunization programs, rubella was endemic worldwide, with regular seasonal peaks occurring in the spring months in temperate climates. In addition, epidemics of rubella occurred at intervals of 6 to 9 years as the pool of susceptible individuals reached a threshold. Epidemics still occur in developing and tropical countries, but the lack of effective monitoring programs, together with the absence of serious clinical symptoms in affected children, has made them difficult to assess.²⁰⁹ Regional variations in the age of onset of rubella, the incidence of the disease, and the appearance and spread of epidemics are determined by population densities, socioeconomic factors, and levels of medical sophistication in a given community. When these rubella outbreaks occur, they are accompanied by birth defects associated with congenital rubella syndrome (CRS). The teratogenic effects of rubella were a significant factor that spurred vaccine development following the rubella pandemic between 1962 and 1965. In this epidemic, an estimated 12.5 million cases of rubella

occurred in the United States alone, resulting in up to 20,000 children born with congenital abnormalities.²⁸ Today, CRS has been reduced to a handful of cases in both Europe and North America, with a declaration by the Centers for Disease Control and Prevention (CDC) in 2005 that endemic CRS had been eliminated from the United States.² However, residual cases are seen in immigrants who may not have been immunized in their country of origin.¹⁸ Despite an increase in rubella vaccination worldwide, less than 40% of the global birth cohort was covered as of 2009.²⁵⁸ Indeed, most of Africa and India and parts of Asia are not vaccinated against rubella (Fig. 24.1). It has been estimated that even in nonepidemic years, there are more than 100,000 infants born with CRS annually.

Age

Prior to the introduction of universal rubella immunization, peak infection occurred in the 5- to 9-year-old age group.¹⁰² After vaccine implementation, the disease shifted from children to young adults until its virtual elimination from Europe and North America in recent years.³⁰ In countries that have not implemented vaccination programs, infection at an early age is still the norm, with high seroconversion rates found in both preschool populations and in the 5- to 9-year-old age group.⁷⁹ In many developing countries, women of childbearing age are susceptible to rubella and the incidence of CRS during rubella outbreaks is 1 to 2 per 1,000 live births.⁵⁸

Origin and Spread of Epidemics

There are no animal reservoirs for RV, and therefore, continued cycling of the virus within the human population is required for perpetuation of the disease between seasons of maximal endemic occurrence. In countries where rubella immunization is not carried out and congenital infection is still common, the surviving infants shed high levels of virus for many months, forming a potential source for maintenance of the virus for relatively long periods. Enhanced vaccination programs have been very effective in disrupting virus circulation in much of the developed world. However, localized outbreaks of rubella still occur with regular frequency in countries where vaccination is practiced. Often, vaccine refusal on the basis of religious grounds is the major factor in such outbreaks. For example, in 2005, 214 cases of rubella occurred in an Amish community in Canada.¹⁴ Similar outbreaks have been reported in the United States among religious communities and Hispanic populations.²⁸ More recently, between 2009 and 2010, an outbreak of 1,900 cases of rubella was reported in Bosnia and Herzegovina, a situation that resulted from decreased vaccine uptake during the 1992–1995 war.¹⁰⁶ Together, these studies demonstrate the importance of maintaining high levels of herd immunity in developed countries, because rubella can be reintroduced into the population by foreign travel or from recent immigrants travelling from endemic areas. To prevent outbreaks, it has been estimated that at least 85% of the population must be immune to RV,⁴ whereas to maintain elimination, a 90% level of immunity among children is required.⁸⁸

Molecular Epidemiology

Based on sequence comparison of the E1 gene, at least 10 genotypes of RV representing two clades (RG1 and 2) have been identified²⁶⁴ (Fig. 24.3). The RG1 clade comprises viral isolates from North America, Europe, and Japan, whereas RG2 was

FIGURE 24.12. Characteristic skin rash on patient with acute rubella.

(Reproduced with permission from Logical Images, Inc.)

identified using isolates from China and India. RG1 and RG2 differ by 8% to 10% at the nucleotide level, as opposed to less than 5% among genotypes within each clade. RG2 has more genetic diversity than RG1 and may in fact consist of multiple clades. These genetic differences have been useful in tracking RV spread around the world and changes in endemic strains over time. Nevertheless, the differences in *E1* genes result in only 1% to 3% substitutions at the amino acid level, attesting to a high degree of genetic conservation between rubella strains. Finally, only one strain from clade 2 contained a mutation in one of the known epitopes defined by monoclonal antibodies, the first indication of a serotype variant.

CLINICAL FEATURES

Acute Rubella

Postnatal infection with RV is usually mild and frequently subclinical.^{7,62} Symptoms, when present, typically include sore throat and low-grade fever, a maculopapular rash, lymphadenopathy, and, in some cases, conjunctivitis and/or arthralgia. The rash (Fig. 24.12) is first seen on the face and spreads in centripetal fashion. The lesions appear as distinct pink maculopapules that fade rapidly over several days. A pronounced posterior cervical and suboccipital adenopathy is often present. In the majority of cases, the clinical syndrome clears in days and is seldom attended by more significant symptoms, but arthropathy, thrombocytopenia, and encephalopathy can occur.¹⁹ However, these serious sequelae and death as a result of RV infection are rare. The course of the acquired infection and the accompanying immune response are shown in Figure 24.13.

The virus is spread through respiratory secretions, and the mucosa of the upper respiratory tract and the nasopharyngeal

lymphoid tissue serve as portals of virus entry as well as the initial sites for viral replication. Spread of virus via lymphatics or a transient viremia then seeds regional lymph nodes. Local replication of virus in these nodes accounts for the posterior cervical and occipital nodal enlargement that typically appears 5 to 9 days before the onset of the rash. The incubation period (approximately 14 days) is followed by the appearance of virus in serum and the onset of viral shedding into the nasopharynx and stool, providing a source of spread to susceptible individuals. High levels of virus can be found in nasopharyngeal

FIGURE 24.13. Time course showing viremic phase, rash, and immunoglobulin M (IgM) and IgG development during acute rubella infection from the time of infection initiation by droplet spray. Patients are infectious and shed virus from the time of infection until 1 to 2 weeks after the appearance of rash. IgM is present by day 10 and peaks around 4 weeks postinfection, by which time low-avidity IgG is also present.

secretions, exceeding 10^5 tissue culture infectious dose 50 (TCID₅₀) per 0.1 mL even in vaccinated individuals.⁷ The viremic phase may be marked by mild prodromal symptoms and malaise. The maculopapular rash appears at 14 to 21 days after natural exposure but somewhat earlier following experimental infection or vaccination. The presence of virus in serum ceases shortly after the rash appears, coincident with the onset of detectable circulating antibodies.

Immune Response

A serologic response can be detected at the onset of rash and continues to evolve over the next few weeks (Fig. 24.13). Generally, immunoglobulin M (IgM) antibody is first detected at 10 days postinfection, after which peak levels occur at 4 weeks postinfection but can persist for more than 7 months after acute infection.^{212,228} By 3 weeks, RV-specific antibodies are present in all immunoglobulin classes, including IgG, IgA, IgD, and IgE. At early stages of primary infection, IgG is of low avidity, maturing gradually during the next 3 months.²⁵

When measured by immunoprecipitation or immunoblot techniques, the majority of the immunoglobulin response appears to be directed at the E1 glycoprotein, with proportionally lesser amounts of the response against E2 or capsid.⁴¹ Interestingly, males have a more rapid and robust antibody response than females, although females have a higher anti-E2 response.¹⁵⁸ Whether there are pathologic consequences of these differences is not known.

Transient depression of lymphocyte responsiveness to mitogenic stimulation follows natural or vaccine infections in children and adults.²⁶ Despite this generalized immune suppression, RV-specific cell-mediated immune responses develop and can be measured *in vitro* within 1 or 2 weeks of onset of clinical illness. The cellular responses wane over the next few years but persist at low levels indefinitely after natural rubella. In contrast, they are difficult to detect following vaccination. More detailed studies have defined the epitope specificity of defined CD4+ and CD8+ T-cell clones^{134,172,175} (see Antigenic Composition and Determinants section).

Complications

JOINT SYMPTOMS

The most common complications of natural rubella are acute arthralgia and/or arthritis, particularly in adolescent and adult women.²¹⁹ Incidence rates for joint involvement range between 30% and 60% during outbreaks. For example, in one report, 52% of adult females and 9% of adult males developed arthropathy, with symptoms being more severe among women.²²⁹ The joint symptoms usually begin within a week of the appearance of the rash and may involve any joint, with the fingers and knees being most commonly affected. Although these symptoms usually resolve within several weeks, they can persist for months or even years, in which case they are episodic. Rarely, chronic severe arthropathy that is significantly disabling has been reported.³⁵ A similar range of less severe symptoms occurs 9 to 27 days following vaccination but is less common than after natural rubella.²²⁹ A report on rubella vaccine-associated arthritis, based on analysis of the Vaccine Adverse Events Reporting System (VAERS) database, has confirmed that rubella vaccine in adult women is associated with chronic arthritis that can persist for at least 1 year.⁷⁶

Factors that affect the incidence of joint symptoms include age and gender,²²⁹ as well as major histocompatibility complex (MHC) type of the infected individual.¹⁵⁵ Hormonal influences also affect the incidence of joint symptoms, with adult females being most susceptible. The underlying pathogenesis of rubella arthritis is unknown, but the mechanism may involve local viral replication. Several groups have reported the isolation of RV from synovial fluids of symptomatic joints for up to a month following acute infection.^{67,162} Virus has also been isolated from PBMCs of symptomatic individuals³⁵ and can be detected in women with chronic arthropathy postvaccination by reverse transcriptase-polymerase chain reaction (RT-PCR) amplification of PBMC RNA using RV-specific primers.¹⁵⁶ Replication and persistence of virus in extra-articular sites and deposition of immune complexes on articular surfaces may therefore play a role in the acute stage.

RV can also infect and persist in joint tissue for prolonged periods *in vitro*, forming foci of infection that are positive for viral antigen.¹⁵² Overall, the body of evidence indicates that RV is a highly arthrotropic virus and a plausible candidate as one of several viral triggers (including human parvovirus, hepatitis C, and human T-cell lymphotropic virus type 1 [HTLV-1]) of chronic degenerative forms of arthritis.

THROMBOCYTOPENIA

A number of different viral infections result in reduced platelets either by inhibiting their production or by causing their lysis.²⁰² For example, binding of viral immune complexes to Fc receptors on the platelet surface triggers immune-mediated clearing of both the complex and its associated platelet.¹¹⁵ This causes a transient asymptomatic depression of thrombocyte counts and is quite common with rubella.⁵² Thrombocytopenic purpura is seen following rubella infection; however, this condition is relatively rare (1 in 1,500 cases)²⁴⁰ and is usually self-limiting. However, it may even occur in the absence of rash. Accordingly, undiagnosed RV infections are likely the cause of some cases of idiopathic thrombocytopenic purpura. Very rarely is epidemic rubella associated with hemolytic anemia.

ENCEPHALOPATHY

The most serious complication of postnatal rubella is postinfectious encephalopathy or encephalomyelitis.¹⁷ Estimated to occur in 1 in 6,000 cases of natural infection, rubella encephalitis is rarely reported in countries with comprehensive vaccination policies. However, occasionally, case reports indicate that this disorder can appear during rubella outbreaks. The symptoms of rubella encephalopathy appear abruptly 1 to 6 days following the onset of rash in an otherwise typical case of rubella. The most frequently encountered symptoms include headache, vomiting, stiff neck, lethargy, and generalized convulsions.²⁵⁰ In rare cases, RV antigens have been detected within brain tissue,⁵¹ and virus has been isolated from cerebrospinal fluid (CSF), indicating that it has the capacity to invade the mature CNS.²²⁰

Postnatal rubella encephalopathy usually requires only supportive treatment, and the disease course is generally concluded within a few days; the survival rate approximates 80%. Among the 20% of patients who do not survive, the disease course typically includes coma, respiratory distress, apnea, and then death, usually within a few days of onset of symptoms.

Congenital Rubella Syndrome

Although postnatal rubella is rarely associated with severe complications, infection *in utero* following transplacental transmission of virus from the mother has dire consequences for the developing fetus. These are reflected in a constellation of symptoms collectively called congenital rubella syndrome.^{52,251}

Pathogenesis of Congenital Rubella Syndrome
